A Data Preprocessing and Model Settings

We use the given well-processed data for WAT17 En-Ja. For other tasks, we apply the byte pair encoding model (Sennrich et al., 2016b) with a joint vocab size of 32K except for WMT18 En-Ru (48K). We experiment with Transformer Base (Vaswani et al., 2017): $d = 512$, $L = 6$, 8 attention heads and FFN size of 2048. Dropout of rate 0.1 is used on residual connections and attention weights. We employ Adam ($\beta_1 = 0.9, \beta_2 = 0.98$) (Kingma and Ba, 2015) for parameter optimization with a scheduled learning rate of warm-up step 4K. Gradient is estimated over roughly 25K target subwords. We average the last 5 checkpoints for evaluation, and use beam search (beam size 4, length penalty 0.6) by default for inference.

B Estimation of the PMI

To evaluate the average point-wise mutual information (PMI) in Table 3, we compare IBDecoder/vanilla SA to its autoregressive counterpart in terms of testing perplexity (ppl). Take SA ($h = 1, c = 2$) as example, we have:

$$\text{PMI}(SA) = \log \text{ppl}(SA) - \log \text{ppl}(\text{Base}) \quad (13)$$

where *Base* denotes the baseline Transformer. The intuition behind our estimation is that Transformer handles neighboring words (y_1, y_2) autoregressively, thus models their joint probability: $p(y_1, y_2) = p(y_1) \cdot p(y_2|y_1)$. Instead, vanilla SA predicts those words independently, i.e. $p(y_1) \cdot p(y_2)$. Comparing the perplexity of SA and Transformer gives an estimation of the average PMI. The method for IBDecoder follows the same spirit.

Priming Neural Machine Translation

Abstract

Priming is a well known and studied psychology phenomenon based on the prior presentation of one stimulus (cue) to influence the processing of a response. In this paper, we propose a framework to mimic the process of priming in the context of neural machine translation (NMT). We evaluate the effect of using similar translations as priming cues on the NMT network. We propose a method to inject priming cues into the NMT network and compare our framework to other mechanisms that perform micro-adaptation during inference. Overall, experiments conducted in a multi-domain setting confirm that adding priming cues in the NMT decoder can go a long way towards improving the translation accuracy. Besides, we show the suitability of our framework to gather valuable information for an NMT network from monolingual resources.

1 Introduction

Priming is a well studied human cognitive phenomenon, founded on the establishment of associations between a stimulus and a response (Tulving et al., 1982). Multiple studies have shown how external stimuli (cues) may have a profound effect on perception. In the case of language translation, external stimuli having such effects are said to prime language understanding and potentially have a impact the actions of a human translator. Imagine for instance a translator facing the ambiguous sentence *I was in the bank*, and the effect on translation accuracy if primed with the cue *river*. Most likely, the human translator would consider the "edge of river" sense rather than "financial institution" for translation. In the context of human translation, cross-lingual priming is particularly effective as cues in the target language may notably influence the final translation word choice.

Several research works have introduced the priming analogy in deep neural networks. In computer vision priming has been broadly studied: for instance, in Rosenfeld et al. (2018), the authors introduce a cue about the presence of a certain class of object in an image that significantly improves object detection performance. Concerning language generation, Brown et al. (2020) use a combination of prompt and example to guide the GPT-3 network when performing a task, where the prompt is a sentence that describes the task (*i.e. "Translate from English to French"*); and is followed by an example of the task (*i.e. "sea otter ⇝ loutre de mer"*). In the context of NMT, experiments reported (Sennrich et al., 2016a; Kobus et al., 2017; Dinu et al., 2019) aim at influencing translation inference with respectively politeness, domain and terminology constraints. More related to our work, (Bulte and Tezcan, 2019; Xu et al., 2020) introduce a simple and elegant framework where similar translations (cues) are used to prime an NMT model, effectively boosting translation accuracy. In all cases, priming is performed by injecting cues in the input stream prior to inference decoding.

In this paper, we extend a framework that mimics the priming process in neural networks, in the context of machine translation. Following up on previous work (Bulte and Tezcan, 2019; Xu et al., 2020), we consider similar translations as external cues that can influence the translation process. We push this concept further: a) by proposing a novel scheme to integrate similar translation cues into the NMT network. We examine the attention mechanism of the network and confirm that priming stimuli are actually taken into account; b) by extending an efficient network to train distributed representations of sentences that are used to identify accurate translations used as priming cues[1]; c) by analyzing how on-the-fly priming compares to micro-adaptation (fine-tuning). Finally, we

[1] https://github.com/jmcrego/cbon

Proceedings of the 5th Conference on Machine Translation (WMT), pages 516–527
Online, November 19–20, 2020.

show that our priming approach can also be used with monolingual data, providing a scenario where NMT can be effectively helped by large amounts of available data. Our proposal does not require to change the NMT architectures or algorithms, relying solely on input preprocessing and on prefix (forced) decoding (Santy et al., 2019; Knowles and Koehn, 2016), a feature already implemented in many NMT toolkits.

The remainder of the paper is organized as follows: Section 2 gives details regarding our priming approach. The experimental framework is presented in Section 3. Results and discussion are respectively in Sections 4 and 5. We review related work in Section 6 and conclude in Section 7.

2 NMT Priming On-the-fly

This section describes our framework for priming neural MT with similar translations. We follow the work by (Bulte and Tezcan, 2019; Xu et al., 2020) and build a translation model that incorporates similar translations from a translation memory (TM) to boost translation accuracy. In this work, TMs are parallel corpora containing translations falling in the same domain as test sentences.

We first describe the methods employed in this work to compute sentence similarity. We then introduce various augmentation schemes considered to prime the NMT network with retrieved similar translations. Overall, we pay special attention to efficiency, since retrieval is applied on a sentence-by-sentence basis at inference.

2.1 Similarity Computation

We detail the sentence similarity tools evaluated in this work. The first employs discrete word representations, while the rest rely on building distributed representations of sentences to perform similar sentence retrieval:

FM: fuzzy matching is a lexicalized matching method aimed to identify non-exact matches of a given sentence. Following Xu et al. (2020), we use `FuzzyMatch`[2], where the fuzzy match score $\mathrm{FM}(s_i, s_j)$ between two sentences s_i and s_j is:

$$\mathrm{FM}(s_i, s_j) = 1 - \frac{\mathrm{ED}(s_i, s_j)}{max(|s_i|, |s_j|)}$$

with $\mathrm{ED}(s_i, s_j)$ being the Edit Distance between s_i and s_j, and $|s|$ is the length of s.

S2V: we use `sent2vec`[3] (Pagliardini et al., 2018) to generate sentence embeddings. The network implements a simple but efficient unsupervised objective to train distributed representations for sentences. The model is based on efficient matrix factor (bilinear) models (Mikolov et al., 2013a,b; Pennington et al., 2014).

Borrowing the notations of Pagliardini et al. (2018), training the model is formalized as an optimization problem:

$$\min_{\boldsymbol{U},\boldsymbol{V}} \sum_{s \in \mathcal{C}} f_s(\boldsymbol{U}\boldsymbol{V}\iota_s)$$

for two parameter matrices $\boldsymbol{U} \in \mathbb{R}^{|\mathcal{V}| \times d}$ and $\boldsymbol{V} \in \mathbb{R}^{d \times |\mathcal{V}|}$, where $\mathcal{V}$ denotes the vocabulary and d is the embedding dimension. Minimization of the cost function f_s is performed on a training corpus $\mathcal{C}$ of sentences s.

In `sent2vec`, ι_s is a binary vector encoding the bigrams in s (bag of bigrams encoding).

CBON: the Continuous Bag of n-grams (`CBON`) model denotes our re-implementation of the previous `sent2vec` model. In addition to multiple implementation details, the main difference is the use of arbitrary large n-grams to model sentence representations, where `sent2vec` only used bigrams.

Both `sent2vec` and `CBON` learn a source (or context) embedding $\boldsymbol{v}_w$ for each n-gram w in the vocabulary $\mathcal{V}$. Once the model is trained, the embedding of sentence s (h_s) is obtained as the average of its n-gram embeddings:

$$\boldsymbol{h}_s = \frac{1}{|R(s)|} \sum_{w \in R(s)} \boldsymbol{v}_w$$

where $R(s)$ is the list of n-grams (including unigrams) occuring in sentence s and $\boldsymbol{v}_w$ is the target embedding of n-gram w.

The similarity score $\mathrm{EM}(s_i, s_j)$ between two sentences s_i and s_j is then defined via the cosine similarity of their sentence vector representations h_i and h_j:

$$\mathrm{EM}(s_i, s_j) = \frac{h_i \cdot h_j}{||h_i|| \times ||h_j||},$$

where $||h||$ denotes the norm of vector h.

Note that models differ in their vocabularies, which are built selecting the most frequent n-grams.

[2] https://github.com/systran/FuzzyMatch

[3] https://github.com/epfml/sent2vec

Both models implement Negative Sampling to avoid the softmax computation.

2.2 Priming Schemes

We now explore various ways to integrate similar translations for priming NMT:

tgt^k we follow here mostly the work of Bulte and Tezcan (2019), where the input sentence in the source language is augmented with the k translations (in the target language) having the highest matching score (FM or EM) in the TM.

In training, sentence pairs (**s**,**t**) are preprocessed as follows: the source sentence **s** is concatenated with translations t^k of the k most similar sentences (s^k) to **s** found in the TM. Augmented translations are sorted by matching score, with $k = 1$ denoting the most similar. Sentences in the source stream are separated using the special token ∘.

$$\texttt{src:} \quad t^k \circ ... \circ t^2 \circ t^1 \circ \mathbf{s}$$
$$\texttt{tgt:} \quad \mathbf{t}$$

In inference, only the source-side is input to the translation network.

In Xu et al. (2020), an issue regarding *unrelated* tokens present in similar translations t^k is raised. The model effectively learns to copy most of the content present in similar translations, but has difficulties to avoid also copying *unrelated* words. Consider for instance the input sentence $s =$ *pertussis vaccin* with similar sentence $s^1 =$ *measles vaccin* and its corresponding translation $t^1 =$ *vaccin contre la rougeole*. Following the **tgt**^{k} scheme, the NMT input consists of:

vaccin contre la rougeole ∘ **pertussis vaccin**

yielding the output: **vaccin contre la rougeole**. The word *rougeole* is actually the translation of an unrelated word (*measles*). The model often copies such *unrelated* tokens (Xu et al., 2020), due to the fact that they are present in the input stream as similar translations (t^k) and are usually semantically related to the correct translation choice (here *coqueluche*, the correct translation for *pertussis*).

tgt^k**+STU** adopts the proposal of Xu et al. (2020) to alleviate the *unrelated word* problem. It relies on an additional source stream (factor) to label related/unrelated tokens. Following on our example, in this scheme the input of the NMT model contains two parallel streams:

src$_1$:	vaccin	contre	la	rugeole	∘	**pertussis**	**vaccin**
src$_2$:	T	T	T	U	T	S	S
tgt:	vaccin	contre	la	coqueluche			

Tokens in the second stream are: S for source tokens, U for unrelated and T for related target tokens. *rougeole* is thus tagged as an *unrelated* word that must not be copied in the translation output. Word embeddings are built after concatenating both factor embeddings. Xu et al. (2020) claim achieving a 8% reduction of unrelated tokens when using this scheme.

Note that this solution is computationally expensive as it requires to identify related/unrelated tokens in each input sentence and in the corresponding similar translations, based in Xu et al. (2020) on word alignments and edit distance computations.

s+t^k the solution proposed in this paper also addresses the *unrelated word* problem, at a much reduced computational cost. It considers both sides of similar translations (s^k and t^k). Training streams take the form:

$$\texttt{src:} \quad s^k \circ ... \circ s^2 \circ s^1 \circ \mathbf{s}$$
$$\texttt{tgt:} \quad t^k \circ ... \circ t^2 \circ t^1 \circ \mathbf{t}$$

In inference, target-side similar translations t^k are used by the model as a target prefix. The initial steps of the beam search use the given prefix $t^k \circ ... \circ t^2 \circ t^1 \circ$ in forced decoding mode, returning to a regular beam search after the last ∘ token is generated. A similar strategy of concatenating previous and current sentences was explored by Tiedemann and Scherrer (2017) in the context of handling discourse phenomena. However, since we use true translation as prefixes, our strategy does not suffer from exposure bias (Ranzato et al., 2016) and the subsequent error propagation problem. Continuing on our running example, during inference the model receives:

$$\texttt{input:} \quad \textit{measles vaccin} \circ \mathbf{pertussis\ vaccin}$$
$$\texttt{prefix:} \quad \textit{vaccin contre la rougeole} \circ$$

the encoder embeds the input stream, and force-decodes the target prefix, before starting the translation generation. Note that during beam search, the decoder has thus access both to all input tokens (s^k and s) as well as to similar translations t^k (in the translation prefix).

Following our approach the NMT model learns to attend to priming cues on both source and target streams. Besides, our solution removes the need to mix source and target vocabularies as in previous schemes.

3 Experimental Framework

3.1 Corpora

We experiment with the English-French language pair and data originating from eight domains, corresponding to texts from three European institutions: the European Parliament (EPPS), the European Medicines Agency (EMEA) and the European Central Bank (ECB); Legislative texts of the European Union (JRC); IT-domain corpora corresponding to KDE4 and GNOME; News Commentaries (NEWS); and parallel sentences extracted from Wikipedia (WIKI). Table 1 contains statistics regarding the corpora used in this work[4] (Tiedemann, 2012). Statistics are computed after splitting off punctuation.

Corpus	#Sents (K)	L_{mean}		Vocab (K)	
		English	French	English	French
Parallel Corpora					
EPPS	1,992.8	27.7	32.0	129.5	149.2
NEWS	315.3	25.3	31.7	90.5	96.7
WIKI	749.0	25.9	23.5	527.5	506.6
ECB	174.1	28.6	33.8	45.3	53.5
EMEA	336.8	16.8	20.3	62.8	68.9
JRC	475.2	30.1	34.5	81.0	83.5
GNOME	51.9	9.6	11.6	19.0	21.6
KDE4	163.9	9.1	12.4	48.7	64.7
Monolingual Corpora					
WIKI	6,426.8	-	24.1	-	1,626.3
NEWS	83,567.8	-	25.5	-	3,444.1

Table 1: Corpora statistics. Note that K stands for thousands and L_{mean} is the average length in words.

Each corpora is considered as a different domain. Training data sets are also employed as TM of the corresponding domain. This is, similar sentences are mined from the same training set that is used to build the model. Note that we also consider monolingual (French) corpora. For the News domain we use all available monolingual WMT news crawl data[5]. For the Wikipedia domain, we use the French-side of the WikiMatrix data (Schwenk et al., 2019a).

We randomly split the parallel corpora by keeping 500 sentences for validation, 1,000 sentences for testing and the rest for training. All data is preprocessed using the OpenNMT tokenizer[6] (conservative mode).

3.2 System Configurations

This section gives learning/inference details of the various systems used in this work.

Similarity

For fuzzy matching **FM** we follow several works (Koehn and Senellart, 2010; Bulte and Tezcan, 2019; Xu et al., 2020) and keep the n-best matches when $\mathrm{FM}(s_1, s_2) \geq 0.5$ with no approximation. Concerning **S2V**, the model is trained with default options during 20 epochs using all training data. We use an embedding dimension of 300 cells. Regarding **CBON**, we learn models using also the entire training data during one epoch (∼50,000 iterations). Similarly to **S2V** we use 10 negative samples per positive word to approximate the softmax, a batch size of $2k$ examples, and embedding size of 300 cells. We build CBON models using 3-grams and 4-grams to enable a comparison with sent2vec which only uses bigrams. All vocabularies are selected keeping the 500,000 most frequent n-grams ($n = 2$ for **S2V** and $n = 3$ and 4 for **CBON**).

For both **CBON** and **S2V** models, we use the 5-best matches when $\mathrm{EM}(s_1, s_2) \geq 0.8$[7]. In all cases, perfect matches are not used for training. Accuracy results on the priming task indicate that 3-grams yield slightly lower accuracy results than those obtained with 4-grams. In the remainder, we always use the 4-gram version of **CBON**.

Sentence Retrieval

To identify similar translations using distributed representations, we use the faiss[8] search toolkit (Johnson et al., 2019) through its Python API with exact *FlatIP* index.

Translation

Our NMT models rely on the Transformer base architecture of Vaswani et al. (2017), implemented in the OpenNMT-tf[9] toolkit (Klein et al., 2017). We use the standard setting of Transformers for all experiments: size of word embedding: 512; size of hidden layers: 512; size of inner feed-forward layer: 2,048; number of heads: 8; number of layers in the encoder or in the decoder: 6. In the **tgt**[1]**+STU** scheme, token (508 cells) and **STU** (4

[7]Optimization experiments on a held-out development set are carried out for both models.

[8]https://github.com/facebookresearch/faiss

[9]https://github.com/OpenNMT/OpenNMT-tf

cells) streams are concatenated, thus using the same number of parameters in all schemes.

For training, we use the Adam (Kingma and Ba, 2015) optimiser with a batch size of $4,096$ tokens. We set the warmup steps to $4,000$ and update the learning rate for every 8 iterations. Models are optimised during $300K$ iterations, using a single NVIDIA V100 GPU. We limit the length of training sentences to 300 BPE tokens (Sennrich et al., 2016c) in both source and target sides to enable the integration of similar sentences. We use a joint BPE-vocabulary of size 32K for both source and target texts. Inference is performed with a beam size of 5 using CTranslate2[10], a custom C++ runtime inference engine for OpenNMT models that enables fast CPU decoding and also implements prefix decoding. For evaluation, we report BLEU (Papineni et al., 2002) scores computed by detokenized case-sensitive `multi-bleu.perl`[11].

We re-implement the work of Farajian et al. (2017) as a contrastive model that we denote μ**adapt**. Note that we only experiment with the basic version of this work, where the closest neighbours of the input sentence are first retrieved from the memory and then used to fine-tune a generic model during 15 additional iterations with a fixed learning rate of 0.0005; the fine-tuned model is then used to produce the translation of the given input sentence. In addition, Farajian et al. (2017) include a variant where learning rate and number of epochs are dynamically adapted considering sentence similarity. Adaptation is run on a sentence-by-sentence basis.

4 Results

Retrieval algorithms employed in this work are significantly faster than NMT Transformer decoding, thus implying a limited decoding overhead.

Table 2 reports efficiency scores (tokens/second) for computing vector representations (Vector), performing sentence retrieval (Retrieval) and translation (NMT) for the `WIKI` test set according to the similarity model and priming schema used. Results show that the computational cost is dominated by the NMT step. This step, in turn, is affected by the length of the input (and prefix) streams.

[10] https://github.com/OpenNMT/CTranslate2

[11] https://github.com/moses-smt/mosesdecoder/blob/master/scripts/generic/multi-bleu.perl

Model	Schema	Vector	Retrieval	NMT
Base	-	-	-	806
FM	**tgt**^{1}	-	25K	750
	s+t^1			687
S2V	**tgt**^{5}	222K	17K	639
CBON	**tgt**^{5}	59K		
	s+t^5			523

Table 2: Efficiency (tokens/second) of each step for different inference configurations. All steps run on CPU (16 cores). K stands for thousands.

Table 3 reports `BLEU` scores for our various configurations, tested on 8 domain-specific test sets. The last column (avg) reports average results. This table also reports the number of input sentences (out of $1,000$) for which at least one similar sentence was retrieved (in a smaller font).

All NMT models are built using the concatenation of the original parallel corpora in Table 1. Our **Base** configuration does not integrate similar sentences in the training data. All other models extend the original corpora with sentences retrieved following similarity methods (Sim) introduced in Section 2.1 and integration schemes presented in Section 2.2 (Scheme).

The second block of results in Table 3 displays scores obtained when performing translations extended with fuzzy matches **FM**. In line with results presented by Xu et al. (2020), using a second stream to mark related/unrelated tokens (**+STU**) yields a boost in performance of around 1 `BLEU` points. When the **s+t**^{1} scheme is used, the average improvement reaches 1.25 `BLEU` points.

The third block compares translation results obtained when identifying similar translations by **S2V** and **CBON**. In both cases, the **s+t**^{5} scheme is used. The choice for 5-best similar translations and $\mathrm{EM}(s_i, s_j) \geq 0.8$ threshold is made after running optimization work on a held out development set. Sentences identified by **CBON** outperform those selected by **S2V**. The idiosyncrasy of fuzzy matching does not enable to find multiple similar sentences for a given input sentence. Overall best results are obtained by the **CBON s+t**^{5} configuration. Note that as expected, the number of similar translations found using distributed representations is larger than those found by fuzzy matching.

Finally, the last block in Table 3 gives results for a system that retrieves similar sentences to dynamically adapt the model on a sentence-per-

sentence basis (Farajian et al., 2017; Li et al., 2018). We show micro-adaptation results when similar sentences are found by **CBON** and **FM** models (μ**adapt**). In our experiments, micro-adaptation does not yield the gains observed with priming methods. As previously stated, the best performing variants of the adaptation method presented in Farajian et al. (2017) were not included in our comparison. Variants employ a dynamically adapted learning rate and number of epochs.

Monolingual Corpora

Retrieval results shown in Table 3 (small font numbers) indicate a reduced number of similar sentences found for some domains (NEWS, EPPS and WIKI). In the context of scarce similar sentences, the boost in translation quality observed for most domains is subsequently reduced. The case of the **NEWS** domain is particularly harmful since worst results are always obtained when compared to our **Base** system.

However, very large monolingual collections of texts exist, far exceeding the amount of available parallel corpora. The latter are more expensive to collect and typically only exist for a limited number of domains and language pairs. With the objective to enhance NMT with monolingual corpora, we now apply the methods presented above to monolingual corpora.

We collect monolingual corpora in the target language (French in this work) and translate each sentence back into English to obtain synthetic parallel data. Similar to back-translation experiments in Sennrich et al. (2016b), we only use original (human-crafted) target-language data. We expect this to add less noise than incorporating synthetic target-language data into the NMT input. Once translated into English, the various priming approaches identify similar synthetic sentences and injects both the synthetic source and original target in the NMT input stream. Note that cross-lingual sentence embedding models exist (Sabet et al., 2019; Schwenk and Douze, 2017; Conneau and Lample, 2019) but our preliminary experiments using these tools did not show satisfactory results.

Thus, we exploit large collections of French texts for the News and Wikipedia domains (as detailed in Table 1) that we translate into English to enable similarity retrieval. Table 4 reports BLEU scores obtained by our best performing network **CBON** following the **s+t**^{5} scheme.

The supplementary number of similar sentences (468 input sentences have similar translations) collected for the WIKI domain over parallel and mono-

lingual[12] corpora (par+mon) yields an improvement of 2 BLEU points. However, very few (97) similar sentences are identified[13] over near 95 million sentences (par+mon), showing a small gain when compared to using only parallel sentences (par). The network does not succeed to outperform the accuracy of the **base** system. As outlined by Bulte and Tezcan (2019) and Xu et al. (2020) the accuracy of networks implementing priming may slightly drop in performance when no similar translations are integrated.

Sim	Scheme	Data	NEWS	WIKI
Base	-	-	**36.66**	35.15
CBON	**s+t**[5]	par	35.41 63	36.38 378
CBON	**s+t**[5]	par+mon	36.05 97	**38.20** 468

Table 4: Translation performance for the NEWS and WIKI domain test sets using similar sentences retrieved from parallel data (par) and from both parallel and monolingual (par+mon) data. The first two rows correspond to experiments already shown in Table 3.

5 Discussion

Unrelated Words

As previously outlined in Section 2, Xu et al. (2020) raised a problem regarding *unrelated* words. It concerns those words that, even through they appear in similar translations, must not be used to translate input sentences. An example of translation with unrelated word is given in Section 2.2 where the input sentence with similar translation:

vaccin contre la rougeole ∘ **pertussis vaccin**

is translated as: **vaccin contre la rougeole**, the right translation being: **vaccin contre la coqueluche**. The error is due to the fact that word *rougeole* is present in the input stream and is semantically related to *coqueluche*. The problem is particularly hurting when it involves keywords (like the proper noun in our example) which convey essential information regarding the meaning of sentences.

The work by Xu et al. (2020), that we denoted **tgt**[1]**+STU**, obtains an average reduction of these erroneous words in the translation hypotheses of 8%. We conduct the same experiment to analyse the performance of the new scheme **s+t**[1] introduced in this work. Table 5 reports the total number of unrelated words in 1-best similar sentences obtained by fuzzy matching[14]. As can be seen, the scheme **s+t**[1] further mitigates the apparition of unrelated words in translations, with a drop of -8.3%.

NMT Attention

We analyse the Encoder and Decoder self-attention layers, aiming to better understand how our **CBON s+t** model configuration makes use of similar translations.

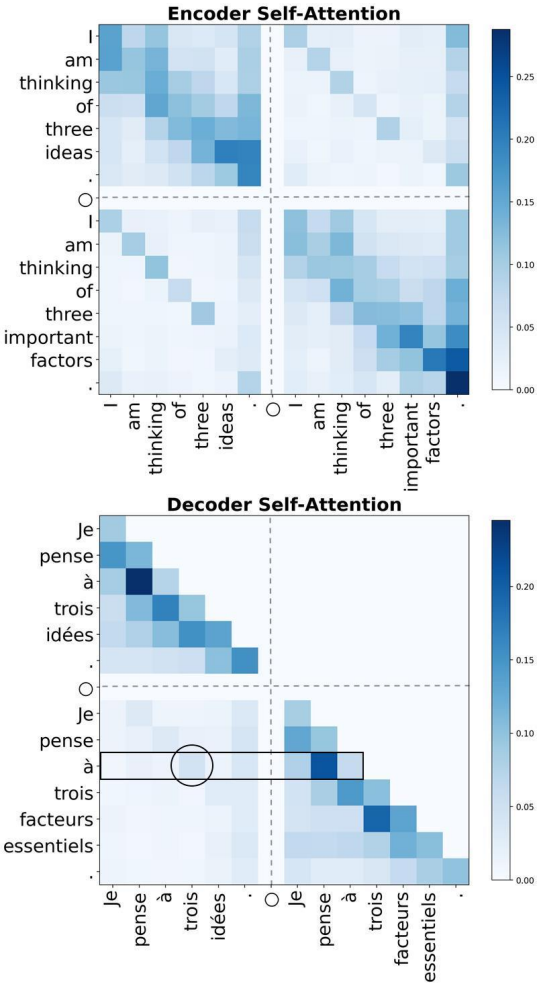

Figure 1: Average attention values of all heads through all layers for the encoder (top) and decoder (bottom). Dashed lines are used to separate similar and input sentences.

Figure 1 displays the attention[15] values for sen-

[12]Test French sentences entirely found in monolingual WIKI corpora are not considered as similar translations.

[13]In all cases we consider similar sentences s_i and s_j when $(\mathrm{EM}(s_i, s_j) \geq 0.8)$

[14]We follow the procedure detailed in Xu et al. (2020) to identify related/unrelated words.

[15]We use the average of all heads through all layers.

Scheme	ECB	EMEA	EPPS	GNOME	JRC	KDE4	NEWS	WIKI	avg
tgt^1+STU	3,555	2,320	312	1,285	3,515	940	39	344	1,538
s+t^1	3,199	1,985	306	1,195	3,413	845	31	310	1,410
unrelated	6,310	4,405	4,405	2,473	6,309	2,358	236	1,591	3,510

Table 5: Number of unrelated words appearing in test sets according to different augmentation schemes. The last row indicates the total number of unrelated words included in 1-best **FM** similar sentences.

tence s = [**I am thinking of three important factors .**] when translated into t = [**Je pense à trois facteurs essentiels .**] using the similar translation example s^1 = [*I am thinking of three ideas .*] and t^1 = [*Je pense à trois idées .*]. For visualization purposes we mask the attention of the sentence separator token ∘.

Concerning the encoder self-attention (top), we can clearly observe that the encoder pays attention to the words in the similar sentence (down-left) when embedding the input sentence (down-right). Equivalently, the decoder self-attention (bottom) also attends to the similar translation (down-left: prefix words generated in forced mode) when producing the translation of sentence s. Note that when the decoder is about to generate the French word *trois [three]*, attention weights (rectangle) are the highest for the preceding words (in particular to *pense [think]*), with *trois* (circle in the similar translation) also receiving a substantial weight. This suggests that the model has learned to use similar translations passed in the form of a target prefix to help generating translations.

Priming Model

The priming network leverages similar sentences from a TM so as to yield more accurate translations. From a mathematical perspective, the search for the best translation $\bar{t}$ is conditioned to the input sentence s as well as to similar pairs of translations s^1 and t^1:

$$\bar{t} = \arg\max_t P(t|s, s^1, t^1)$$

to facilitate reading we use one single similar translation (s^1 and t^1) rather than k-best translations.

To evaluate the intuition that $P(t|s, s^1, t^1)$ gives better translations than $P(t|s)$, we report the average of $\log P(t|s, s^1, t^1)$ computed by **CBON s+t^5** and of $\log P(t|s)$ computed by **Base** over test sets sentences with similar sentences translations.

Table 6 reports the difference between the token average of $\log P(t|s, s^1, t^1)$ and the token average of $\log P(t|s)$. More precisely, for each test sentence s, we compute the log probability of predicting reference t, we then sum all the calculated log probabilities and divide the sum by the total number of tokens in the references. For each test set, we computed the average log probability of model **CBON s+t^5** and **Base**. We report the difference in the average of both models. Results indicate that $\log P_{\textbf{CBON s+t}^5}(t|s^1, s, t^1)$ are actually greater than $\log P_{\textbf{Base}}(t|s)$ in most cases, with the exception of EPPS and NEWS for which the base system yields higher probabilities. We observe a strong correlation between values reported and the gap in BLEU score for the same model configurations.

WIKI	0.009

Table 6: Differences of token average log probability between **CBON s+t^5** and **Base** model.

Similarity over Synthetic Sentences

Results in Table 4 show a clear boost in performance (∼2 BLEU points) when making use of synthetic translations of the WIKI monolingual data set. We now want to measure the noise introduced by synthetic translations when compared to human translations. Thus, we consider the input sentences of the WIKI test set for which we found similar sentences in both the parallel (human translation) and monolingual (synthetic translation) corpus (279 sentences).

Results in Table 7 show a clear drop in BLEU scores when using synthetic matches. As expected, machine translation quality degrades the results

of similarity search which in turns provides less valuable similar translations.

Priming sentences	WIKI
par (human)	52.50
mon (synthetic)	49.94

Table 7: Results for a reduced test set (279 sentences) using **CBON** when priming with human and synthetic (back-translated) translations.

6 Related Work

Our work relates to the ideas introduced in Bulte and Tezcan (2019) and Xu et al. (2020). Both of them leverage similar translations from parallel corpora and inject similar sentences in the NMT network. While Bulte and Tezcan (2019) integrates fuzzy matches into the NMT model by concatenating similar translations to source sentences, Xu et al. (2020) extended the framework by adding additional source side features to distinguish between related and unrelated words, employed distributed sentence representations. A similar idea is also explored in Schwenk et al. (2019b), where the authors use multilingual sentence embeddings to retrieve pairs of similar sentences and train models uniquely with such sentences.

Previously, Niehues et al. (2016) augmented input sentences with pre-translations generated by a phrase-based MT system. Our work, in contrast, integrates similar sentences in both source and target sides and employs similar translations found in parallel as well as monolingual data sets.

A similar strategy of concatenating previous and current sentences was explored by Tiedemann and Scherrer (2017) further evaluated by Bawden et al. (2018) in the context of tackling discourse phenomena. Our work employs force decoding to allow including true translations in the decoder target-side. Thus, avoiding the error propagation problem (Ranzato et al., 2016) of longer sequences in auto-regressive models.

Bapna and Firat (2019) propose a neural MT model that incorporates retrieved neighbours relying on local phrase level similarities. Using deep pre-trained models (Peters et al., 2018; Radford et al., 2019; Devlin et al., 2019; Le et al., 2020; Conneau and Lample, 2019) to compute contextualized sentence representations has become common fashion in recent works (Feng et al., 2020; Chang et al., 2020). However, deep models suffer from computation complexity when applied on-the-fly for inference. We propose an extension of `sent2vec` (Pagliardini et al., 2018) to compute sentence representations that also inherits from the computationally efficient bilinear models (Mikolov et al., 2013a,b; Pennington et al., 2014).

Similar to our work, Farajian et al. (2017) and Li et al. (2018) retrieve similar sentence to dynamically adapt each individual input sentence. Farajian et al. (2017) obtains best performance when tuning the adaptation learning rate and number of epochs according to level of similarity between the input and retrieved sentences. In Xu et al. (2019) the model is dynamically adapted to a entire test set to reduce adaptation time.

In computer vision, priming network has been recently studied. For the object detection task , Rosenfeld et al. (2018) primed the network via an external information that affects all the processing layers. Upon processing each image in the network, Rosenfeld et al. (2018) also presented the network with the category of the object in the image; this information is injected at all layers.

7 Conclusions

Inspired by the human psychological phenomenon of priming, we have presented a simple framework for priming NMT networks. Following other research works, we used similar translations as priming cues to influence the NMT network. We presented a novel method that injects similar translations in the NMT network as prefixes of the decoder. The proposed method obtains higher translation accuracy results and reduces the undesirable effect observed in previous methods of copying unrelated words when performing translations.

We also proposed an extension to `sent2vec` that considers larger n-gram orders. It allows us to identify similar sentences (cues) that yield higher accuracy rates as measured on translation test sets.

We evaluate results on a multi-domain setting using a single model trained on a heterogeneous data set, built from multiple corpora and domains, achieving better results when compared to previous micro-adaptation approaches. In addition, we showed the suitability of our approach to gather valuable information from large monolingual corpora.

In our future work, we would like to explore alternative algorithms to compute distributed sentence representations from word embeddings, such

as TF-IDF. Furthermore, we would like to consider source sentence coverage when selecting n-best similar translations. As regards distributed representations we plan to experiment with cross-lingual networks to retrieve similar translations directly from human-crafted monolingual data in order to eliminate the noise introduced by synthetic translations.

Subword Segmentation and a Single Bridge Language Affect Zero-Shot Neural Machine Translation

Annette Rios[1] and **Mathias Müller**[1] and **Rico Sennrich**[1,2]
[1]Department of Computational Linguistics, University of Zurich
[2]School of Informatics, University of Edinburgh

Abstract

Zero-shot neural machine translation is an attractive goal because of the high cost of obtaining data and building translation systems for new translation directions. However, previous papers have reported mixed success in zero-shot translation. It is hard to predict in which settings it will be effective, and what limits performance compared to a fully supervised system. In this paper, we investigate zero-shot performance of a multilingual EN↔{FR,CS,DE,FI} system trained on WMT data. We find that zero-shot performance is highly unstable and can vary by more than 6 BLEU between training runs, making it difficult to reliably track improvements. We observe a bias towards copying the source in zero-shot translation, and investigate how the choice of subword segmentation affects this bias. We find that language-specific subword segmentation results in less subword copying at training time, and leads to better zero-shot performance compared to jointly trained segmentation. A recent trend in multilingual models is to not train on parallel data between all language pairs, but have a single *bridge* language, e.g. English. We find that this negatively affects zero-shot translation and leads to a failure mode where the model ignores the language tag and instead produces English output in zero-shot directions. We show that this bias towards English can be effectively reduced with even a small amount of parallel data in some of the non-English pairs.

1 Introduction

Zero-shot translation has first been introduced by Firat et al. (2016) and refers to the ability of a multilingual NMT model to translate between all its source and target languages, even those pairs for which no parallel data was seen in training. In the simplest setting, all parameters in the network are shared between the different languages and the translation is guided only by special tags to indicate the desired output language (Johnson et al., 2017; Ha et al., 2016). While this capability is attractive because it is an alternative to building N^2 dedicated translation systems to serve N languages, performance on zero-shot pairs tends to lag behind pivot translation. Recent papers, such as Arivazhagan et al. (2019), Gu et al. (2019) and Zhang et al. (2020), have suggested training techniques to improve the generalization to unseen language pairs, but performance varies considerably across settings.

In this paper, we examine in detail the behavior of the multilingual model proposed by Johnson et al. (2017) on zero-shot translation directions. Our experiments show the following:

- Translation quality for zero-shot language pairs is highly unstable between different training runs, and between training checkpoints, which calls for more rigour to avoid false positive results.
- The incorrect copying of source text into the output is affected by the extent of subword copying at training time, and can be reduced by performing language-specific subword segmentation.
- English-centric models have a tendency to produce English text for non-English input. Multi-bridge models that include data from non-English pairs mitigate this problem.

Overall, we observe improvements of 8.1 BLEU (15.9→24.0) on 6 zero-shot directions with simple changes to the multilingual training setup.

2 Related Work

Our experiments are based on the multilingual model proposed by (Johnson et al., 2017; Ha et al.,

Proceedings of the 5th Conference on Machine Translation (WMT), pages 528–537
Online, November 19–20, 2020.

2016): A single model is trained on multiple language pairs with a standard encoder-decoder architecture, all parameters in the network are shared for all languages, including the vocabulary. An artificial target language token determines the output language. We prefix this special token to the source sentence as in Johnson et al. (2017). The major advantage of this model lies in its simplicity, since it does not require changing the architecture or training objective.

Several recent studies have explored approaches to improve generalization to zero-shot language pairs, for example through semi-supervised training (Gu et al., 2019; Currey and Heafield, 2019; Zhang et al., 2020) or alignment of encoder representations (Arivazhagan et al., 2019).

Our study is concerned with data conditions that enable zero-shot generalization for multilingual NMT, specifically preprocessing and data settings. While initial work used separate encoders and decoders for different languages (Firat et al., 2016), sharing of encoder and decoder parameters was established by Johnson et al. (2017); Ha et al. (2016) and has since been widely adopted. Johnson et al. (2017) use a shared subword segmentation model across languages, and this strategy is followed by later work (e.g. Aharoni et al., 2019; Zhang et al., 2020). Ha et al. (2016) do not share embeddings across languages, but use language-specific codes. We will show that both strategies cause errors.

In terms of data settings, the number of languages involved in multilingual models has increased from 3–4 (Firat et al., 2016; Johnson et al., 2017) to over 100 (Aharoni et al., 2019). The most popular setup are English-centric datasets, where the model is trained on translations between English and a number of other languages. A multi-way parallel corpus between 5 languages has been provided for the IWSLT17 multilingual task (Cettolo et al., 2012). Results on this dataset show strong zero-shot generalization, close or even exceeding the supervised condition (Lakew et al., 2017), but multi-way parallel corpora are only available in small amounts and specific domains, so we investigate alternatives to English-centric models that do not rely on multi-way parallelism.

3 Data and Models

Following Aharoni et al. (2019), our baseline setup is English-centric. For training, we use 5 million parallel sentences per language pair for English↔{French,Czech,German,Finnish} from WMT (Barrault et al., 2019). For all zero-shot language pairs, we sample test sets from OPUS (Tiedemann, 2012), see Table 1 for details.

To indicate the target language, we prefix a language tag on the source side (e.g. <2en>). Following Johnson et al. (2017), we segment all data with a byte-pair encoding model trained jointly on the training data in all five languages (Sennrich et al., 2016), with a threshold of 32k BPE operations. All our systems are base Transformers (Vaswani et al., 2017) implemented in Sockeye (Hieber et al., 2018), trained with early stopping based on BLEU on a development set that consists in equal parts of parallel sentences from all trained translation directions. See Appendix A and B for training details.

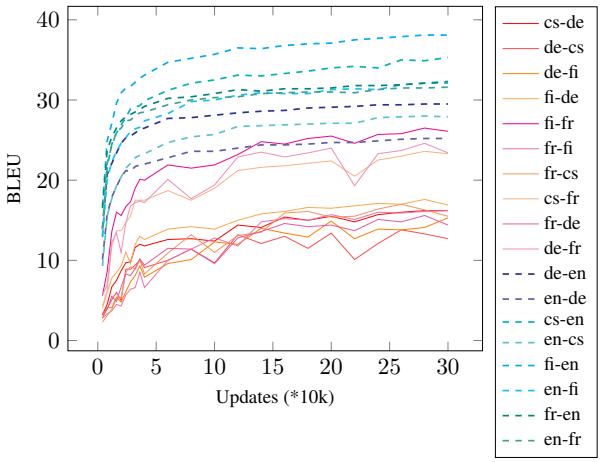

Figure 1: Baseline BLEU scores on test set as a function of training time. Dashed lines: trained pairs; solid lines: zero-shot pairs.

4 Baseline Experiments

BLEU[1] on zero-shot pairs is relatively unstable, see Fig. 1: while BLEU on the trained pairs increases steadily during training (dashed lines), performance on unseen language pairs fluctuates considerably, as also observed by Aharoni et al. (2019). Furthermore, multiple training runs result in relatively large differences in BLEU on the zero-shot directions. Across three training runs, average BLEU varies up to 0.24 points on trained language pairs (standard deviation: 0.12), but up to 6.28 BLEU on zero-shot pairs (standard deviation: 3.14) – see Table 2 for full results. We suspect that this fluctuation is due to the fact that the model is not op-

timized on zero-shot directions: models converge to different local minima that may be similarly good for trained pairs, but with no mechanism that stabilizes generalization to zero-shot pairs. If not stated otherwise, we will report the mean and standard deviation of three training runs with different seeds throughout the paper.

As an alternative to zero-shot translation, we report results obtained via pivot translation through English (e.g. German-English-Czech). On our data set, this approach works better than zero-shot translation. Pivot translation is stable across training runs, with a standard deviation of 0.19.

5 Copy Bias and Language-Specific Subword Segmentation

One failure mode we observe in zero-shot translation is over-copying of the input.[2] We suspect that for the translation of zero-shot directions, the model relies heavily on (sub-) words in the vocabulary that are shared between languages. To test this hypothesis, we train two models with language-specific subword segmentation:

a) a model with language-specific subword seg-

mentation and no vocabulary overlap. We limit BPE operations to 10k per language.

b) similar to model a), with the exact same subword segmentation, but with vocabulary overlap.

For model a), we remove any potential vocabulary overlap by adding a language identifier to each subword. For instance, consider the preposition *in* in German and English: instead of one token *in*, the network vocabulary has an entry for *in#de#* and an additional entry for *in#en#*. This corresponds to the language-specific coding introduced by Ha et al. (2016).

For model b), we split words with the same language-specific BPE models as for a), but we allow vocabulary overlap, i.e. homographic forms in different languages are represented by a single entry in the network's vocabulary. This results in a vocabulary size of ∼50k for model a), whereas for model b), the vocabulary amounts to a total of ∼36k subwords.

Table 3 shows that removing vocabulary overlap does not affect the trained language pairs greatly, however, the effect on the zero-shot directions is quite harsh: For the first evaluation of model a), we remove only the correct target language tag (i.e. homographic forms with wrong language tag count as wrong), while for the second evaluation, we remove all language tags from the translations (i.e. homographic forms in other languages count as correct). In the first case, the model averages at only 4.7 BLEU on zero-shot directions, however, the more lenient second evaluation results in better scores (12.7 BLEU). This difference is due to the fact that the no-overlap model tends to produce a lot of English subwords (marked by #en#), especially for proper names and numbers.[3]

The second evaluation improves BLEU because the no-overlap model will often output the correct form, e.g. for proper names, if the word in the target language has the same spelling as in English.

Model b), with language-specific BPE and overlapping vocabularies, represents a compromise between a fully shared representation and fully language-specific coding. We hypothesize that allowing some vocabulary overlap helps aligning the representation between sentences with the same meaning in different languages, which is also supported by the effectiveness of cross-lingual pretraining with shared vocabularies for unsupervised MT and cross-lingual transfer (Conneau and Lample, 2019). We observe that models with jointly trained BPE develop a strong bias towards copying the input in zero-shot conditions. However, using language-specific BPE reduces the subword overlap between source and target sentences at training time, and consequently reduces this copying behavior at test time (see Table 4). Model b) indeed performs better (+5.1 BLEU) on the zero-shot directions than the original baseline with shared BPE (see Table 3).

[3]This essentially means that the strict evaluation gives us a more realistic estimate of the translation quality we can expect if the source and target language do not happen to share word forms, e.g. languages in different scripts.

	trained	zero-shot

6 Multi-Bridge Models

A common issue in zero-shot translation is output in the wrong language. Previous work has addressed this with semi-supervised training (Gu et al., 2019; Arivazhagan et al., 2019; Zhang et al., 2020). We explore whether the recent trend to train English-centric models is to blame for this behavior. In most cases, the model will wrongly produce English output in zero-shot directions, since for all non-English languages, English was the only target language seen in training.

We suspect that adding even a small amount of parallel data in pairs without English will improve

generalization, make models more sensitive to the language tag, and reduce the amount of English translations in the zero-shot directions. To test this hypothesis, we collect a small amount of parallel data in German-Czech and Finnish-French[4] and train our model with the additional language pairs. This new model has seen all non-English languages paired with exactly one other non-English language, but it still has zero-shot directions in de↔fr, fr↔cs and de↔fi. We use language-specific BPE segmentation and thus use the model with the best zero-shot performance from Table 3 as baseline.

The results in Table 5 show that even a small amount of parallel data in non-English language pairs increases generalization to unseen translation directions. The increase in BLEU scores for the newly added pairs de↔cs and fi↔fr are expected, but the new model also performs better on cs↔fr, de↔fr and fi↔de (+3.1 BLEU on average).

Following Zhang et al. (2020), we use the Python

Table 6: Percentage of output produced in the correct target language (tgt), English, and the source language (src) in zero-shot translation according to automatic language identification. Models from Table 5.

version of langdetect[5] to estimate the number of translations in the correct language. Even though the amount of parallel data in de↔cs and fi↔fr was small compared to the directions with English (350k vs. 5 million sentence pairs), the new model is less likely to produce output in the wrong target language, as shown in Table 6.

7 Comparison to Back-Translation and Encoder Alignment

Previous work on the zero-shot generalization of multilingual NMT systems has proposed back-translation or changes to the training objective to improve translation in unsupervised directions. While we consider our proposed solutions on the data side to be complementary, and easier to adopt widely, we still want to discuss the question how our solutions compare to previous work, and whether they can be combined.

7.1 Back-Translation

Previous work has used fine-tuning with synthetic, back-translated data for translation directions that were unseen at training time (Gu et al., 2019; Currey and Heafield, 2019; Zhang et al., 2020). While this can mitigate the problem of producing output in the wrong language, this approach is sensitive to the zero-shot translation quality of back-translation.[6] We perform experiments following Gu et al. (2019) where we create synthetic corpora for all zero-resource directions via back-translations (250k sentences per translation direction), and fine-tune our models on the concatena-

[5]https://github.com/Mimino666/langdetect

[6]Unless back-translation is done via a pivot language, but note that Gu et al. (2019) report slightly better results for direct zero-shot back-translation.

[1] used as development set for early stopping for +bt

Table 7: Zero-resource translation performance (BLEU) with single-bridge and multi-bridge multilingual models, fine-tuned with a cosine loss to reward encoder representation alignment (+align), and back-translation for zero-resource translation directions (+bt).

tion of this data, plus 250k sentence pairs per supervised translation direction. As base system for both back-translation and fine-tuning, we consider both our single-bridge and our multi-bridge system.

As stopping criterion during fine-tuning, we use BLEU on the Finnish↔German test set, one of the zero-resource language pairs. This leaves us with 5 translation directions that are still purely zero-resource.

7.2 Encoder Alignment

Arivazhagan et al. (2019) propose to use cosine distance as an additional loss term for multilingual models. The cosine distance loss encourages the model to produce encoder representations for sentences in the source language that are similar to the encoder representation of the same sentence in the target language. This, directly and indirectly, rewards similarity of encoder representations across all languages. We implement cosine loss in Sockeye, but instead of normalising sequence lengths by max pooling like Arivazhagan et al. (2019), we average encoder states, as proposed by Gouws et al. (2015). We introduce a new hyperparameter λ that scales cosine distance (CD) loss w.r.t. the standard cross-entropy (CE):

$$\mathcal{L} = (1 - \lambda) * CE + \lambda * CD \quad (1)$$

We train models with $\lambda = 0.5$. As in our experiments with back-translation, we do not train from scratch, but fine-tune each of the single-bridge and multi-bridge models with a patience of 10.[7]

7.3 Results

Results are shown in Table 7. The gains from using more than one bridge language and back-translation are cumulative: Both the single- and the multi-bridge baseline improve with encoder alignment and back-translation, but the multi-bridge performs better overall in zero-resource directions.

Aligning encoder representations leads to an increase of 0.8 BLEU for the zero-shot directions for the single bridge data. In the multi-bridge scenario however, the effect of the additional loss is smaller (+0.3 BLEU on average). Table 7 contains only results for models with language-specific subword segmentation; but preliminary experiments show that aligning encoder representations of one of the baselines from Table 2 with jointly trained BPE gives a similar result: Encoder alignment alone does not fix the underlying issue caused by vocabulary overlap and English-centric models, even though we observe an increase of $\sim$ 1.5 BLEU points in zero-shot directions over the baseline.

Back-translation leads to an average improvement of 0.7 BLEU with single-bridge data, and 1.2 BLEU with multi-bridge data. On the fully supervised pairs English↔{Czech,German,Finnish,French}, we observe a performance drop by 0.7–0.9 BLEU with back-translation. Again, back-translation alone does not seem to solve the issues of single-bridge setups, and the model benefits from additional supervised translation directions.

On the 6 remaining zero-shot translation direc-

[7] In a new training run with random initialization, the encoder produces highly similar representations for all languages from the start. Arivazhagan et al. (2019) report that fine-tuning yields better results.

tions, our pivoting baseline (Table 2) achieves an average BLEU of 23.7. Our best system with multi-bridge data and back-translation achieves 25.2, and thus outperforms our pivoting baseline by 1.5 BLEU.

8 Conclusions

We analyze the importance of shared subwords in multilingual models and find that language-specific BPE segmentation helps to reduce the amount of untranslated segments in zero-shot directions. Furthermore, we explore whether the tendency to produce the wrong output language can be attributed to using English as the only bridge language, and show that even with a small amount of additional training data in non-English language pairs, generalization to unseen translation directions improves as the model is less likely to produce output in the wrong language.

Compared to previous work, the methods we propose are easier to implement, since they only concern data collection and pre-processing, and result in higher gains for zero-shot directions. They are also compatible in principle with approaches that introduce new training objectives or model modifications, and we report best results when fine-tuning a multi-bridge model with back-translation for zero-resource translation directions.

For future work, we are interested in testing the effects of subword regularization (Kudo, 2018; Provilkov et al., 2020) on zero-shot translation performance, and scaling multi-bridge setups to massively multilingual settings.

A Model Size and Training

All models are trained with the Sockeye toolkit (Hieber et al., 2018)[8] on 5 Tesla-V100 (16GB) GPUs for 4-5 days.

model type	number of parameters
1 joint bpe baseline	60,516,602
2 language specific bpe, no vocabulary overlap	69,728,543
3 language specific bpe, vocabulary overlap	62,470,619
4 language specific bpe, vocabulary overlap, multi-bridge	62,490,626

Table 8: Number of Parameters per Model Type. Numbers vary between models due to different vocabulary sizes. Vocabulary is built automatically based on training data, therefore, 4 has a slightly larger vocabulary than 3. Cosine-loss models have the same number of parameters as 3 and 4.

model type	best checkpoint and BLEU					
	seed=1		seed=2		seed=3	
1 joint bpe baseline	106	30.7	95	30.9	94	31.3
2 language specific bpe, no vocabulary overlap	66	29.3	115	31.0	60	30.0
3 language specific bpe, vocabulary overlap	90	30.3	120	31.0	55	29.4
4 language specific bpe, vocabulary overlap, multi-bridge	117	29.3	80	28.6	59	28.2

Table 9: Best checkpoint according to BLEU on development set (patience=10). Sentence pairs in the development sets are identical for each model, however the dev set for model 4 contains additional samples in cs↔de and fi↔fr.

Look It Up: Bilingual and Monolingual Dictionaries Improve Neural Machine Translation

Abstract

Despite advances in neural machine translation (NMT) quality, rare words continue to be problematic. For humans, the solution to the rare-word problem has long been dictionaries, but dictionaries cannot be straightforwardly incorporated into NMT. In this paper, we describe a new method for "attaching" dictionary definitions to rare words so that the network can learn the best way to use them. We demonstrate improvements of up to 3.1 BLEU using bilingual dictionaries and up to 0.7 BLEU using monolingual source-language dictionaries.

1 Introduction

Despite its successes, neural machine translation (NMT) still has unresolved problems. Among them is the problem of rare words, which are paradoxically very common because of Zipf's Law. In part, this is a problem intrinsic to data-driven machine translation because the system will inevitably encounter words not seen in the training data. In part, however, NMT systems seem particularly challenged by rare words, compared with older statistical models.

One reason is that NMT systems have a fixed-size vocabulary, typically 10k–100k words; words outside this vocabulary are represented using a special symbol like UNK. Byte pair encoding (BPE) breaks rare words into smaller, more frequent subwords, at least allowing NMT to see them instead of UNK (Sennrich et al., 2016). But this by no means solves the problem; even with subwords, NMT seems to have difficulty learning translations of very rare words, possibly an instance of catastrophic forgetting (McCloskey and Cohen, 1989).

Humans deal with rare words by looking them up in a dictionary, and the idea of using dictionaries to assist machine translation is extremely old. From a statistical perspective, dictionaries are a useful complement to running text because the uniform distribution of dictionary headwords can smooth out the long-tailed distribution of running text. In pre-neural statistical machine translation systems, the typical way to incorporate bilingual dictionaries is simply to include them as parallel sentences in the training data. But (as we show), this does not work well for NMT systems.

We are aware of only a few previous attempts to find better ways to incorporate bilingual dictionaries in NMT. Some methods use dictionaries to synthesize new training examples (Zhang and Zong, 2016; Qi et al., 2018; Hämäläinen and Alnajjar, 2019). Arthur et al. (2016) extend the model to encourage it to generate translations from the (automatically extracted) dictionary. Post and Vilar (2018) constrain the decoder to generate translations from the dictionary. What these approaches have in common is that they all treat dictionary definitions as target-language text, when, in fact, they often have properties very different from ordinary text. For example, CEDICT defines 此致 (*cǐzhì*) as "(used at the end of a letter to introduce a polite salutation)" which cannot be used as a translation. In the case of a monolingual source-language dictionary, the definitions are, of course, not written in the target language at all.

In this paper, we present an extension of the Transformer (Vaswani et al., 2017) that "attaches" the dictionary definitions of rare words to their occurrences in source sentences. We introduce new position encodings to represent the nonlinear structure of a source sentence with its attachments. Then the unmodified translation model can learn how to make use of this attached information. We show that this additional information yields improvements in translation accuracy of up to 3.1 BLEU. Because our method does not force dictionary definitions to be treated as target-language text, it is generalizable to other kinds of information, such as monolingual source-language dictionaries, which yield smaller improvements, but still as much as 0.7 BLEU.

Proceedings of the 5th Conference on Machine Translation (WMT), pages 538–549
Online, November 19–20, 2020.

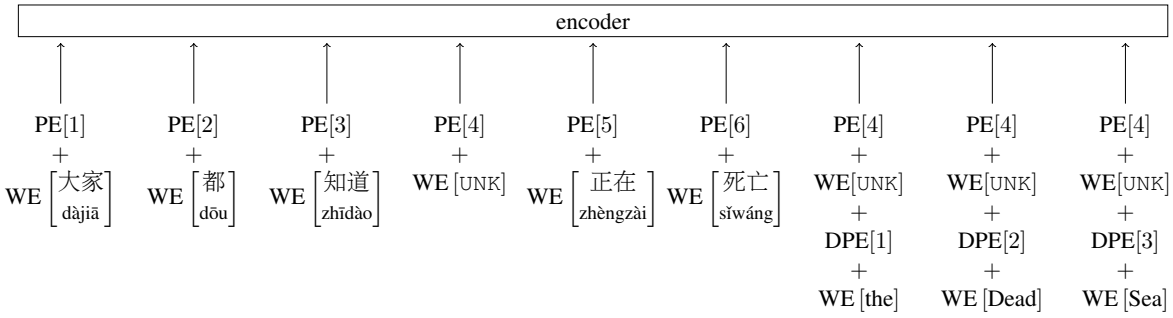

Figure 1: Our method attaches dictionary definitions to rare words. Here, the source sentence is 大家 都 知道 死海 正在 死亡 (*dàjiā dōu zhīdào Sǐhǎi zhèngzài sǐwáng*, *Everyone knows that the Dead Sea is dying*). WE$[f]$ is the embedding of word f, PE$[p]$ is the encoding of position p, and DPE$[q]$ is the encoding of position q within a dictionary definition. The rare word 死海 (*Sǐhǎi*) is replaced with UNK and defined as *the Dead Sea*. The words of the definition are encoded with both the position of the defined word (4) and their positions within the definition.

2 Methods

Our method is built on top of the Transformer (Vaswani et al., 2017). For each unknown source word with an entry in the dictionary, we attach the first 50 tokens of the definition (discarding the rest of the definition) to the source sentence. As described below, we encode the definition so as to differentiate it from the source sentence proper and to record which source word the definition is attached to. We leave the task of deciding whether and how to use the definition up to the translation model, which we use without any modifications.

2.1 Position encodings

To differentiate the attached definitions from the source sentence itself, we use special position encodings.

An ordinary word f at position p is encoded, as usual, as $\mathrm{E}[f] = \mathrm{WE}[f] + \mathrm{PE}[p]$, where WE is the word embedding and PE is the usual sinusoidal position encoding (Vaswani et al., 2017).

Suppose that word f at position p has an attached definition. Then word d at position q of the definition is encoded as

$$\mathrm{E}[d] = \mathrm{WE}[f] + \mathrm{PE}[p] + \mathrm{WE}[d] + \mathrm{DPE}[q],$$

where DPE is a position encoding scheme different from PE. We experimented with several schemes for DPE; in the experiments below, we learned a different encoding for each position (Gehring et al., 2017).

See Figure 1 for an illustration of the encoding of an example source sentence. Note that once all words have received their position encodings, their order does not matter, as the Transformer encoder is order-independent.

2.2 Subword segmentation

To apply our method on data that has been segmented using BPE, we face two new problems. First, since very few words are replaced with UNK, it is not sufficient only to attach definitions to UNK. How do we decide which words to attach definitions to? Second, if a word has been split into multiple subwords, the definition does not have a single attachment position. How do we represent the attachment position when encoding the definition?

To choose which words to define, we use a simple frequency threshold. We scan the data (after tokenization/segmentation but before BPE) for matches with the dictionary, including multi-word matches. If any substring of the source sentence matches a headword in the dictionary and occurs in the training data k or fewer times, we attach its definition. The threshold k can be tuned on the development data.

To attach a definition to a substring with more than one token, we simply fuse all the tokens in the substring into a single token, which often (but not always) then falls out of the vocabulary and is therefore changed to UNK. We attach the dictionary definition to this single token, which represents the whole word or expression.

For example, in the sentence in Figure 1, BPE splits 死海 (*sǐhǎi*) into 死@@ 海 (*sǐ@@ hǎi*) (where @@ is the marker that typical implementations of BPE use to indicate subword splits). Assuming that 死海 occurs k or fewer times, we fuse it back into a single token, which gets changed into UNK. Then the dictionary definition is attached as described above.

3 Experiments

In this section, we describe our experiments on Chinese-English and German-English translation, comparing our method (which we call *Attach*) against two baselines. One baseline is the standard Transformer without any dictionary information (which we call *Baseline*). The other baseline is the standard Transformer with the bilingual dictionaries included as parallel sentences in the training data (which we call *Append*).

3.1 Data: Chinese-English

For Chinese-English, we used the UM-Corpus[1] (Tian et al., 2014), which has about 2M sentence pairs in eight different domains. Since rare words may be more frequent in certain domains, testing our model on different types of data may highlight the conditions where dictionaries can be helpful. We excluded the Microblog domain because of its length (only 5000 lines). For each of the other domains, we split the data into three parts: the first roughly 80% for training (*train*), the next 10% for development (*dev*), and the last 10% for testing (*test*). The task *UM-all* combines all eight domains. The UM-Corpus provides a test set, which we used (*test*), and we split the provided training data into two parts, the first 90% for training (*train*) and last 10% for development (*dev*). The exact line counts and other statistics are shown in Table 1.

We used the Stanford segmenter[2] (Chang et al., 2008) for the Chinese data and the Moses tokenizer[3] for the English data.

As a dictionary, we used CC-CEDICT,[4] which has 116,493 entries. Each entry has a traditional Chinese headword (which we delete), a simplified Chinese headword, a pronunciation (which we delete), and one or more definitions. We process the definitions as follows:

- Remove substrings of the form *abbr. for* c, where c is a Chinese word.
- If a definition contains *see* c or *see also* c, where c is a Chinese word, replace it with the definition of c.
- Remove everything in parentheses.
- Remove duplicate definitions.
- If the entry has no definitions left, delete the whole entry.
- Concatenate all the definitions into a single string.

The resulting dictionary has 102,567 entries, each consisting of a Chinese headword and a single English definition. We segmented/tokenized these in the same way as the parallel data. The average definition length is five, and the maximum definition length is 107.

[1] http://nlp2ct.cis.umac.mo/um-corpus/

[2] https://nlp.stanford.edu/software/segmenter.shtml

[3] http://www.statmt.org/moses/

[4] https://www.mdbg.net/chinese/dictionary?page=cedict, downloaded 10/2018.

For example, consider the following CEDICT entries, where we have already removed traditional Chinese characters and pronunciations for clarity.

三自 /abbr. for 三自爱国教会, Three-Self Patriotic Movement/
U盘 /USB flash drive/see also 闪存盘
闪存盘 /USB flash drive/jump drive/thumb drive/memory stick/

After cleaning, these would become

三自 Three-Self Patriotic Movement
U盘 USB flash drive jump drive thumb drive memory stick
闪存盘 USB flash drive jump drive thumb drive memory stick

3.2 Data: German-English

For German-English, we used the Europarl V7 dataset.[5] We tokenized both sides of the data with the Moses tokenizer. Due to the size of the original Europarl dataset and the increased runtime from our method, we ran some experiments on only the first 200k lines of the dataset, denoted in result tables as *Europarl-small*, while the full Europarl data is called *Europarl-all*. We split both into three parts: the first roughly 80% for training, the next 10% for development, and the last 10% for testing. Some statistics of the data are shown in Table 1.

We used the German-English dictionary from Stardict,[6] which is derived from Freedict[7] and has 81,628 entries. In this dictionary, the headwords have notes in parentheses indicating things like selectional restrictions; we deleted all of these. Unlike with CEDICT, we did not delete any material in definitions, nor did we resolve cross-references, which were very rare. As before, we removed blank entries and merged multiple definitions into a single line. We tokenized both headwords and definitions with the Moses tokenizer. The final dictionary size is 80,737 entries, with an average definition length of 2.9 and a maximum definition length of 88.

For example, the entry:

(Aktien) zusammenlegen to merge (with)

would become

zusammenlegen to merge (with)

Europarl-all	30.0	29.8	30.1

Table 2: Results on word-based translation. Our method (Attach) significantly improves over the baseline in all tasks. Appending the dictionary to the parallel data (Append) performs worse in all tasks except in News; differences are significant for all tasks except UM-all and Thesis.

3.3 Implementation and details

We used Witwicky,[8] an open-source implementation of the Transformer, with all of its default hyperparameters. We use the same random seed in each experiment. We modified it to attach dictionary definitions as described above. The code and our cleaned dictionaries are available under an open-source license.[9]

For BPE-based translation, we used joint BPE with 16k operations. For word-based translation, we set each system's vocabulary size close to the vocabulary size of the corresponding BPE-based system. For example, the Spoken dataset with 16k BPE applied to the training data has 25,168 word types, so we limited the word-based model to 25,000 word types. The vocabulary size we chose for each data set is shown in Table 1.

For all tasks except UM-all and Europarl-all, we trained for 20 epochs, and used the model with the highest dev BLEU to translate the test set. Due to the massive increase in training data on the UM-all and Europarl-all datasets, we only trained for 10 epochs. Otherwise, the settings are the same across all experiments.

We report case-insensitive BLEU scores of detokenized outputs against raw references. We perform significance testing with bootstrap resampling using 1000 samples, with a significance level of 0.05.

Table 3: Comparison of variations of our method on word-based translation.

Method	UM-Spoken Dev BLEU
Baseline	14.2
Attach to fused unknown words	14.8
+ fused multi-word expressions	14.8

Table 4: Comparison of variations of our method on BPE-based translation.

3.4 Results: Word-Based

Table 2 shows results on word-based translation. The *Append* column shows that simply appending the bilingual dictionary to the parallel training data is not helpful, for all tasks except News; these differences are significant for all tasks except UM-all and Thesis. By contrast, our method improves accuracy significantly over the baseline across all tasks.

We also compared against some variations of our method. First, CEDICT has definitions for single words as well as multi-word expressions. In our original setup, we only look up unknown single words, so the definitions for multi-word expressions are never used. To fully utilize the dictionary, we tried changing the source data by taking every substring that matches a dictionary entry and fusing it into a single token, which would often, but not always, fall out of the vocabulary and be changed to `UNK`. When more than one match was possible, we chose the longest possible match, breaking ties arbitrarily. However, we found that fusing phrases did not perform as well as just fusing words (Table 3). We also tried attaching dictionary definitions to all tokens, not just `UNK` tokens. Unfortunately, this also did not perform as well (Table 3).

3.5 Results: BPE-Based

As described in Section 2.2, we fuse subwords in order to attach definitions. Again we must first decide whether we wanted to fuse multi-word expressions.

Task	Baseline	Append	Fuse	Attach
Spoken	16.6	14.7	16.3	17.0
Science	11.6	9.6	13.8	14.7
Laws	29.0	26.8	29.0	30.0
News	11.8	10.9	11.3	13.3
Education	12.9	12.3	12.2	14.2
Subtitles	20.0	17.3	19.7	21.3
Thesis	15.3	14.2	14.9	15.5
UM-all	19.8	19.7	19.3	21.4
Europarl-small	32.6	30.8	33.4	33.5
Europarl-all	35.3	36.0	36.1	36.5

Table 5: Results on BPE-based translation. Our method (Attach) improves significantly over the baseline in Europarl-small and all Chinese-English tasks, whereas appending the dictionary to the parallel data (Append) performs worse, significantly so for Europarl-small and all Chinese-English tasks except UM-all. For Europarl-all, Append is significantly better. The Fuse column shows the effect of fusing words that would receive definitions, without actually attaching the definitions.

On the dev set, both methods have comparable performance (Table 4). Since we were interested in using as much of the dictionary as possible, we chose the model that fuses phrases.

As described in Section 2.2, we fuse subwords and attach definitions only for words whose frequency falls below a threshold. To tune this threshold, we trained models using thresholds of $k = 5$, 10, 15, 20, 50, 100, and ∞, and measured BLEU on the development set (Figure 2). We found that for Chinese-English, $k = \infty$ was best, but for German-English, $k = 5$ was best.

The results are shown in Table 5. As before, we compared against the two baselines (*Baseline* and *Append*). To tease apart the effect of fusing words and adding dictionary definitions, we also tested a model where all words that would receive definitions are fused, but the definitions are not actually attached (*Fuse*). Finally, we tested our model (*Attach*). On Chinese-English, our model improved significantly over the baselines across all tasks, whereas appending the dictionary to the parallel data did worse, significantly so on all tasks except UM-all. On German-English, the results on Europarl-small were similar, with Append doing significantly worse and our model doing significantly better. Interestingly, on Europarl-all, Append does significantly better than the baseline.

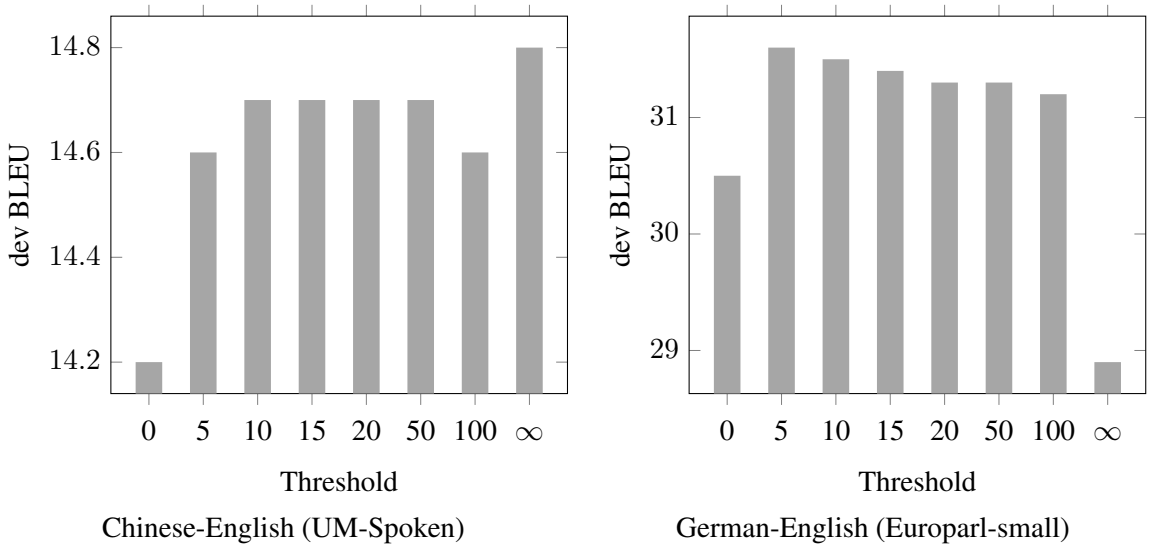

Figure 2: Effect on dev BLEU scores of the frequency threshold below which we fuse a word and attach its definition. These scores are used to choose the threshold that is used in Table 5.

3.6 Monolingual dictionaries

Because our dictionary-attachment method does not make any assumptions about the form of the definitions, we can apply it to monolingual source-language dictionaries as well. Monolingual source-language dictionaries are a natural resource for human translators, but we're not aware of previous research that uses them in data-driven machine translation. For many languages and language pairs, we expect them to be much more comprehensive than bilingual dictionaries. Our monolingual dictionary is the 汉语辞海 (*Hànyǔ Cíhǎi*),[10] which has a total of 380,579 entries. We removed pronunciations and concatenated multiple definitions into a single line. We did not resolve any cross-references in this dictionary, and we removed all entries with empty definitions. This gives us a final dictionary size of 358,234 entries.

We experimented with using this dictionary on the Spoken and Science UM datasets. The results are shown in Table 6. Although, as expected, it does not help as much as a bilingual dictionary, it does help on three out of four tasks we tried. All differences in this table are statistically significant.

		Test BLEU	
Segmentation	Dictionary	Spoken	Science
word	none	13.6	8.0
	zh–zh	14.3	8.4
	zh–en	15.4	9.2
BPE	none	16.6	11.2
	zh–zh	15.2	11.6
	zh–en	17.0	14.7

Table 6: Attaching a monolingual Chinese-Chinese dictionary improves over the baseline in three out of four tasks, although not as much as a bilingual Chinese-English dictionary does. All differences are statistically significant.

4 Analysis

To further examine how our methods improve translation, we looked at some examples in our UM-Spoken dev set, shown in Table 7 (word-based) and Table 8 (BPE). The (UNK) tag next to dictionary definitions indicates that the word is outside of the system's vocabulary.

In the first example, 对称性 (*duìchènxìng*, symmetry) is unknown to the word-based systems. Adding the definition to the parallel training data (*Append*) does not help word-based translation because the word remains unknown, whereas our model correctly generates the translation *symmetry*. With BPE, the word is broken into three pieces, so that the Append system can correctly generate the word *symmetry*. But the third character (性, *xìng*) can also mean "sex," and together with the following character (性感, *xìnggǎn*) can mean "sexy." This explains why the Append system incorrectly adds the words *of sex*.

In the second example, 火药 (*huǒyào*, gunpow-

Table 7: Examples from word-based systems on the UM-Spoken data. In the first and second examples, the unknown words 对称性 (*duìchènxìng*) and 火药 (*huǒyào*) cannot be translated by the baseline, even with the dictionary in the parallel data (Append). Our model successfully incorporates the dictionary definition *symmetry*, but not *gunpowder*, because it is unknown. In the third example, the definition is not suitable as a direct translation of the unknown word 打量 (*dǎliàng*), but our model generates the word *looked*, apparently by picking out the word *look* from the definition and inflecting it correctly for the context.

Table 8: Examples from BPE-based systems on the UM-Spoken data. In the first two examples, the baseline system, even with the dictionary in the parallel data (Append), tries to translate the pieces of unknown words separately and incorrectly (e.g., *fire*, *pills*, *sex*). Our model is able to translate the first and third examples correctly as in Table 7, as well as the second example.

der) is unknown, and the definition word *gunpowder* is also unknown. So none of the systems are able to translate this word correctly (though arguably our system's generation of UNK is preferable). When we switch to BPE, our model generates the correct translation. The other systems fail because this word splits into two very common words, 火 (*hǔo*, fire), and 药 (*yào*, medicine), which the system tries to translate separately.

The third example shows what happens when we have a long definition that contains useful information, but is not suitable as a direct translation of the unknown word 打量 (*dǎliàng*). Here we see that our attachment model generates the word *looked*, apparently by picking out the word *look* from the definition and inflecting it correctly for the context. No other models were able to generate a word with a similar meaning.

Please see Appendix A for visualizations of the encoder-decoder attention for these three examples.

We also looked at a few examples from the Europarl-small dev set, shown in Table 9 and 10. In the first example, the definition *omission* was out of vocabulary, so our model was not able to perform any better than the baselines. However, in the BPE systems, our model was able to properly translate *Auslassung* to *omission* while none of the other baseline systems was able to. In the second example, we see something similar in the word-based system. The Baseline and Append models were unable to generate the correct translation of *Alternativlösung*, but our method was. With BPE, all systems (even Baseline) were able to translate the word correctly.

5 Discussion

In Section 1, we mentioned several other methods for using dictionaries in NMT, all of which treat dictionary definitions as target-language text. An alternative approach to handling rare words, which avoids dictionaries altogether, is to use word embeddings trained on large amounts of monolingual data, like fastText embeddings (Bojanowski et al., 2017). Qi et al. (2018) find that fastText embeddings can improve NMT, but there is a sweet spot (likely between 5k and 200k lines) where they have the most impact. They also find that pre-trained embeddings are more effective when the source and target languages are similar.

We, too, experimented with using fastText word embeddings in our NMT system, but have not seen any improvements over the baseline – perhaps because our datasets are somewhat larger than those used by Qi et al. (2018). We also experimented with using dictionaries to improve word embeddings and found that the present approach, which gives the model direct access to dictionary definitions, is far more effective.

The most significant limitation of our method is runtime: because it increases the length of the source sentences, training and decoding take 2–3 times longer. Another limitation is that the effectiveness of this method depends on the quality and coverage of the dictionaries.

In the future, we plan to experiment with additional resources, like thesauruses, gazetteers, or bilingual dictionaries with a different target language. Second, from our examples, we see that our model is able to select a snippet of the definition and adapt it to the target context (for example, by inflecting words), but further analysis is required to understand how much the model is able to do this. Finally, our method currently requires an exact match between a dictionary headword and a source word; we plan to extend the model to enable matching of headwords with inflected forms.

6 Conclusion

In this paper, we presented a simple yet effective way to incorporate dictionaries into a Transformer NMT system, by attaching definitions to source sentences to form a nonlinear structure that the Transformer can learn how to use. We showed that our method can beat baselines significantly, by up to 3.1 BLEU. We also analyzed our system's outputs and found that our model is learning to select and adapt parts of the definition, which it does not learn to do when the dictionary is simply appended to the training data. We also found that our method has some potential to work with monolingual dictionaries.

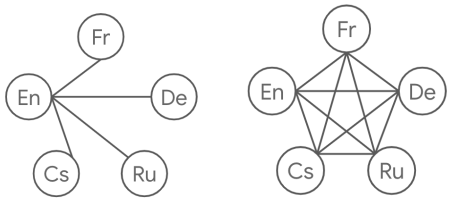
Abstract

Multilingual Neural Machine Translation (MNMT) models are commonly trained on a joint set of bilingual corpora which is acutely English-centric (i.e. English either as the source or target language). While direct data between two languages that are non-English is explicitly available at times, its use is not common. In this paper, we first take a step back and look at the commonly used bilingual corpora (WMT), and resurface the existence and importance of implicit structure that existed in it: multi-way alignment across examples (the same sentence in more than two languages). We set out to study the use of multi-way aligned examples to enrich the original English-centric parallel corpora. We reintroduce this direct parallel data from multi-way aligned corpora between all source and target languages. By doing so, the English-centric graph expands into a complete graph, every language pair being connected. We call MNMT with such connectivity pattern complete Multilingual Neural Machine Translation (cMNMT) and demonstrate its utility and efficacy with a series of experiments and analysis. In combination with a novel training data sampling strategy that is conditioned on the target language only, cMNMT yields competitive translation quality for all language pairs. We further study the size effect of multi-way aligned data, its transfer learning capabilities and how it eases adding a new language in MNMT. Finally, we stress test cMNMT at scale and demonstrate that we can train a cMNMT model with up to 111∗112=12,432 language pairs that provides competitive translation quality for all language pairs.

1 Introduction

Multilingual machine translation (Dong et al., 2015; Firat et al., 2016a; Johnson et al., 2017; Aharoni et al., 2019), which can serve multiple language pairs with a single model, has attracted much attention. In contrast to bilingual MT systems which can only serve one single language pair, multilingual models can serve $O(N^2)$ language pairs (N being the number of languages in a multilingual model) (Zhang et al., 2020).



(a) English-centric (b) Complete

Figure 1: Source-target translation graphs in MNMT. Solid lines indicate that there exist direct parallel data. When there is no line connecting any two languages, zero-resource or zero-shot approaches are employed.

The amount of available training data can differ a lot across language pairs and the majority of available MT training data is English-centric (Tiedemann, 2018; Arivazhagan et al., 2019b) which in practice means that most non-English language pairs do not see a single training example when training multilingual models (see Figure 1a). As a consequence, the actual performance of language pairs that do not include English on the source or target side lags behind the ones with large amounts of training data. Further, when increasing the number of languages, it gets (a) impractical to gather training data for each language pair and (b) challenging to find the right mix during training. Which is why models tasked with direct translation between non-English pairs either resort to bridging (pivoting) through a pivot language (Habash and Hu, 2009), or make use of synthetic parallel data (via back-translation) (Firat et al., 2016b; Chen et al., 2017) or study the problem under zero-shot settings (Johnson et al., 2017; Ha et al., 2016).

In this study, we make use of the potential pre-

Proceedings of the 5th Conference on Machine Translation (WMT), pages 550–560
Online, November 19–20, 2020.

existing multi-way property in the training corpora and generate as many direct training examples from pre-existing English-centric training data. If we can find training examples for each language pair in a multilingual mix, we call this model complete Multilingual Neural Machine Translation (cMNMT). cMNMT is then trained on all bilingual pairs between source and target languages by utilizing multi-way aligned training examples that consist of translations of the same sentence into multiple languages. We resurface multi-way aligned training examples by aligning training examples from different language pairs when either their source or target sides are identical (ie. pivoting through English, for German→English and English→French to extract German–French–English examples).

To make use of this data, the model samples a source and target language from the set of multi-way aligned corpus during training, which allows the model to see language pairs where originally no training data existed (missing connections in Figure 1a). As our experiments support, this method enables us to get access to training data for all tested language pairs (generating a complete graph (Figure 1b)). We will show that it is possible to generate a complete graph for at least a 6-language WMT setup. Some of the WMT training data is multi-way parallel by construction. Nevertheless, we show that we also find many training examples where the source and target origin from different sources. We further show on our 112 languages internal dataset, that we can find sufficient training data for over 12,000 language pairs by only providing 111 English-centric training corpora. This result indicates that it is possible to generate direct training data for many language pairs without the need for crawling new training examples. Our experiments suggest that before falling back to methods like zero-shot translation, you should investigate the structure of your pre-existing training data.

To address the problem of finding the right mix of examples from different language pairs during training, we further introduce a hierarchical sampling strategy that is language-specific (as opposed to being language pair specific). In addition to fixing some chronic issues of MNMT (i.e. low quality for out of English translation (Firat et al., 2016a; Johnson et al., 2017; Arivazhagan et al., 2019b)), the proposed sampling strategy efficiently ensures all source-target pairs are covered.

Experiments demonstrate that we can train a cMNMT model on a 30-language-pair WMT setup that outperforms bilingual and multilingual baselines as well as bridging on all non-English language pairs. We further show that the performance of the English language pairs stay stable and do not suffer from the changes in both the training data and the new training data sampling strategy. Furthermore, we share experiments at scale by demonstrating that we can train a cMNMT model that can serve 12,432 language pairs.

Our contribution is three-fold:

- We show that we can find a lot of training examples for all language pairs in a multilingual mix by only pivoting pre-existing English-centric training data. We further show that many of the extracted examples originate from different data sources and this method could scale to many more datasets. We also support these findings with experiments on our internal dataset, where we were able to find training data for all 12,432 language pairs.
- We demonstrate that cMNMT outperforms bilingual baselines, multilingual baselines as well as bridging on all non-English language pairs while keeping translation performance on English-centric language pairs.
- We introduce a new sampling strategy that is purely based on the target language instead of language pairs and does scale to MNMT models which hundreds of languages.

2 A Peek at Multi-way Aligned Examples in Bilingual Corpora

We choose six languages Czech (cs), English (en), French (fr), German (de), Spanish (es) and Russian (ru) from the public WMT datasets. The selection of the languages was driven by the fact that the WMT 2013 evaluation campaign (Bojar et al., 2013) released a multi-way test set for these six languages. As training data, we used WMT 2013 for Spanish, WMT 2014 for German, WMT 2015 for French, and WMT 2018 for Czech and Russian.

We can construct non-English bilingual training examples by pairing the non-English sides of two training examples with identical English translations. Table 1 shows the number of bilingual training examples that we could potentially extract from the English-centric training data. The

number of training examples for each non-English language pair varies from at least 0.3 million (Russian-German) to up to 4.8 million sentence pairs (Russian-French).

ru	0.9	0.3	33.5	4.4	4.8	

Table 1: WMT: Available training data (in million) after constructing non-English examples from English-centric examples with identical English side.

Some of the extracted non-English training examples are multi-way parallel by construction. The UN corpus is a 6-way parallel corpus, and three of the languages (English, French and Spanish) are in our 6-language mix. A portion of the Europarl corpus is again multi-way aligned. Nevertheless, a good amount of the extracted data is coming from different sources. Table 2 shows the number of non-English bilingual training examples separated by the two sources they originated from.

Table 3 shows how many translations are available for each sentence in the WMT training data. The majority (123 million) of the multi-way aligned examples do only have translations into two languages. As our original bilingual training data is English-centric, all of the 123 million training examples consist of an English sentence and a translation into one of our five other languages. A total of 13 million multi-way aligned examples are available in at least three languages. Further, Figure 2 shows the average number of translations conditioned by the language. Both Spanish and German have, on average more than three translations. In comparison, the majority of the multi-way aligned examples with Czech or English on the target side are bilingual (having only two translations). Our study resurfaced the inherent multi-way aligned information in the commonly used set of parallel corpora instead of discarding this information.

3 Complete Multilingual NMT

We call MNMT models that are trained for all possible source–target pairs as complete MNMT as all languages are connected via training data (also see Figure 1). Before going into details of how the missing pairs' data gathered, we recap MNMT first.

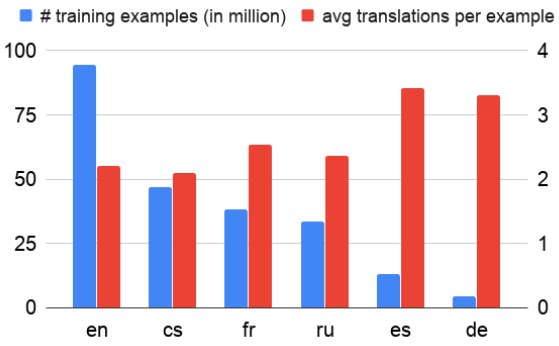

Figure 2: Average translations per multi-way aligned example conditioned on the target language.

Multilingual NMT Framework MNMT (Firat et al., 2016b; Johnson et al., 2017) is an extension of bilingual NMT which uses a single model to translate between multiple languages. The model parameters are trained on a joint set of bilingual corpora from different language pairs. Given the data imbalance across the different corpora, it is common to oversample the language pairs with less training data (Lee et al., 2016; Johnson et al., 2017). For a given language pair p, let $D(p)$ be the size of the available parallel corpus, the sample probability with a temperature T is defined as

$$p_p = \left(\frac{D(p)}{\sum_q D(q)}\right)^{\frac{1}{T}} \quad (1)$$

As a result, $T = 1$ corresponds to the actual data distribution, and $T = 100$ corresponds to (almost) an equal number of samples for each language pair). In addition to being able to translate language pairs that the model was trained with, the model can also translate between language pairs never seen explicitly during training which is often referred as zero-shot translation (Johnson et al., 2017; Ha et al., 2016).

Using multi-way aligned data in MNMT Instead of only relying on bilingual corpora, bilingual examples from different language pairs with identical target sentences can be combined into a single multi-way aligned training example. An example is given in Table 4. By comparing the English sides of the Spanish–English and the German–English corpora, we extract a multi-way aligned example that contains translations into all three languages.

X-Y	*Bleib sicher* ↔ Stay safe
Z-Y	Mantente segura ↔ Stay safe
X-Y-Z	*Bleib sicher* ↔ Mantente segura ↔ Stay safe

Table 4: The two German–English and Spanish–English bilingual training examples can be combined into one multi-way aligned training example that consists of translations into all three languages.

While we can extract direct training data for any source-target pair among the languages considered, the total number of language pairs increases quadratically. The vanilla language pair based sampling strategy in Eq. (1) with adjustable temperature is capable of balancing low-high resource language pairs during training. However, we noticed a critical failure mode, which is further amplified in complete MNMT. The language-pair based sampling strategy (regardless of the temperature being used) *over-represents English* in English-centric models. Notice half of the languages have English on the source side, with the other half on the target side. This over-representation yields a schedule of examples for the encoder (resp. for the decoder) to see English examples half of the time throughout the entire training process. As a result, trained models end up favouring English either on the source and/or target. Although the implications on the encoder could be minimal, over-exposing English examples to the decoder curtail the learning signal when the target language is non-English. We hypothesise that this imbalance in the learning signal with respect to the target language is one of the roots of poor translation quality of multilingual models when translating out of English (Firat et al., 2016a; Johnson et al., 2017; Arivazhagan et al., 2019b).

To alleviate the *over-representation of English* with the language-pair based sampling strategy, we propose a hierarchical sampling strategy with two levels: i) we choose a target language (based on a temperature-based schedule), ii) uniformly sample a source language. Formally, for a given target language l, let $D(l)$ be the size of the available training examples with target language l, the sample probability with a temperature T is defined as

$$p_l = \left(\frac{D(l)}{\sum_q D(q)}\right)^{\frac{1}{T}} \quad (2)$$

During training, the scheduler samples a batch of training examples based on the target language only, as opposed to source-target language pair specific sampling. After choosing a target language, for each multi-way aligned example, we randomly (uniformly) pick one of the translations as the source sentence.

4 Experiments

We use a public transformer implementation with the transformer-big model size (Vaswani et al., 2017) for all multilingual setups. All bilingual models use a vocabulary of 32,000 subwords, while all multilingual models use a vocabulary of 64,000 subword units. All multilingual models are trained for 500,000 updates using an average batch size of around 33,000 sentences (∼1 million tokens). All bilingual models are trained for 400,000 steps as they converged earlier using a batch size of around 8,000 sentences (∼260,000 tokens). Due to the data imbalance across languages, we use a

temperature-based data sampling strategy to oversample low-resource language pairs in standard MNMT models (Equation 1) and low-resource target languages in cMNMT models (Equation 2). We use a temperature of $T = 5$ in both cases. All multilingual models add a token at the beginning of the input sentence to specify the required target language. All BLEU (Papineni et al., 2002) scores are calculated with sacreBLEU (Post, 2018).[1]

4.1 Baselines on WMT

We train several baselines: (i) bilingual models, (ii) multilingual models based on English-centric data, and (iii) bridging non-English language pairs.

Bilingual Baselines We train two bilingual baselines (using either transformer-base or transformer-big) for each language pair. In addition to training baselines on the original English-centric WMT data, we also train models for non-English language pairs on the extracted direct data (see Table 1). We experimented with several dropout rates for both setups and found that dropout=0.1 works best for transformer-base while dropout=0.3 works best for transformer-big. As can be seen from Table 5 and Table 6, the experiments suggest that the translation quality of the non-English language pairs is far behind the ones for English-centric language pairs. As an example, the translation quality between German and Russian reaches 6-7 BLEU only.

Table 5: BLEU scores on newstest2013 of bilingual models trained with the transformer-base architecture.

Multilingual Baselines We train a multilingual NMT model on the original WMT English-centric training data. BLEU scores are summarized in Table 7. All language pairs with English as the source or target language perform comparably well from at least 24.5 BLEU (English→Russian) up to 34.9 BLEU (English→French). The BLEU scores of non-English language pairs are consistently lower (which can be explained as a lack of supervision during training) and can be as low as 4.1 BLEU for Spanish→Czech or as high as 24.4 BLEU for French→Spanish.

Table 7: BLEU scores on newstest2013 of a MNMT model trained on English-centric training data. All non-English language pairs are unseen during training and BLEU scores measure zero-shot performance.

Bridging (Pivoting) Baselines The quality of MNMT is still behind the one from bilingual baselines for most of the language pairs (comparing Table 6 and Table 7). Nevertheless, having a single NMT model for each language pair is impractical, especially when increasing the number of language pairs. An alternative approach is called bridging (Cohn and Lapata, 2007; Wu and Wang, 2007; Utiyama and Isahara, 2007). For the bridging approach, we compromise and train only English-centric models. To enable the translation between non-English language pairs, the source sentence cascades through the source→English and English→target systems to generate the target sentence. This simple process has several limitations: (i) translation errors accumulate in the pipeline, (ii) decoding time gets doubled since inference has to be run twice, (iii) bridging through a morphologically low language (i.e. English), important information could be lost (i.e. gender). The BLEU scores (Table 8) for all non-English pairs are higher compared to all previous baselines. We can reach acceptable translation quality even for

[1] sacreBLEU signatures: BLEU+case.mixed+lang.SRC-TGT+numrefs.1+smooth.exp+SET+tok.intl+version.1.2.20

German→Russian, where our direct training data is scarce. We use the bridging baseline to compare our cMNMT models in the rest of the paper.

4.2 Complete MNMT Models on WMT

Without adding new training data and taking into account the multi-way property of the data, we train a complete multilingual NMT system (cMNMT, see Section 3). We compare the performance of cMNMT with the best baseline model that is based on bridging (Table 8) and report BLEU and delta BLEU numbers in Table 9. The BLEU scores for the non-English language pairs go up from at least 1.4 BLEU for Russian→Spanish up to 5.0 BLEU for Czech→Russian. We changed the sampling strategy for our cMNMT models to be conditioned on the target language only (Section 3). As a result, English has been seen less often as the target language when compared to a standard MNMT setup. Interestingly, this seems to affect only the performance of Russian→English, which shows a decrease of 1 BLEU point. The other language pairs with English as the target language are keeping their translation quality.

When comparing our cMNMT model to the English-centric baseline (Table 7), we see an average BLEU increase of 14.6 BLEU for all non-English language pairs. It is worth noticing that every language pair has now at least 22 absolute BLEU points. Interestingly, the absolute BLEU scores in each row (translations into the same language) are much closer, suggesting a more universal input representation.

5 Analysis and Discussion

To further understand the impact of multi-way aligned examples on NMT, we run a couple of additional experiments.

Training Data Sampling Strategy In Section 3, we did introduce our new training data sampling strategy that is based on the target language only. This change was mainly driven by the fact that having a language-pair conditioned schedule is not scalable when building a system of 12,432 language pairs. Instead of finding a good sampling weight for each of the 12,432 language pairs, we only need to find a suitable mix for the 112 target languages. Further, we have more control over how often each target language will be seen during training. To see the impact of this change, we train an MNMT system on the joint set of the 30 different bilingual corpora with a standard language-pair based temperature scheduling scheme and compare it to a cMNMT model. We used temperature 5 in both setups. ΔBLEU numbers for each language-pair can be seen in Figure 3. The language-conditioned temperature scheduling increases BLEU scores for 29 out of 30 language-pairs with larger gains for the low-resource language-pairs. This experiment suggests that a target language based temperature scheduling is not only simpler but also performs better on average.

Separate Multi-way Aligned Examples We test the transfer learning capability of cMNMT by training a cMNMT model only on the 13 million multi-way aligned examples that have translations in at least three languages (see Table 3). In other words, we remove all training examples that are only available in English and one additional language. If no transfer learning is happening, the English-centric scores will decrease while the BLEU numbers of the non-English language

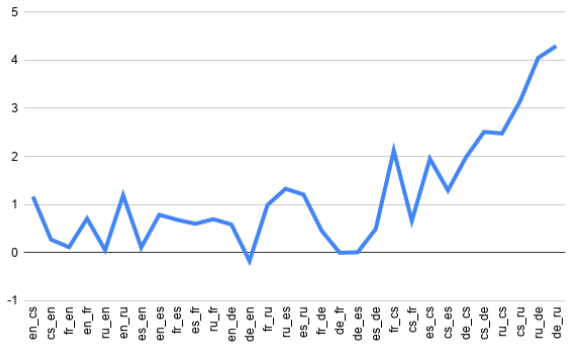

Figure 3: ΔBLEU scores for a target language based versus a language-pair based temperature schedule.

pairs are not affected. Experimental results can be seen in Table 10. Interestingly, we find that the performance of all language pairs is similarly affected. This indicates that transfer learning is happening between the language pairs and that non-English language pairs benefit from having more English-centric data.

To further study this effect, we reverse that experiment and remove all examples that have translations into more than two languages. This experiment investigates if the non-English language pairs in a standard MNMT model can benefit from having training examples with identical English sides. Experimental results can be found in Table 11. The BLEU scores for English-centric language pairs drop by 0.9 points on average while the performance of non-English language pairs decreases by 1.6 BLEU on average.

Table 11: BLEU on newstest2013 for a model trained on 2-way data only. Small numbers are the difference (ΔBLEU) between the vanilla MNMT model (Table 7).

Leave N-Out We further investigate the transfer learning capability of our approach by training several cMNMT models on different amounts of training data. We start with a cMNMT model trained on English-centric bilingual training data only. This setup ensures that all languages have been seen on both the source and target side during training. We further group the remaining multi-way aligned training examples by target language and add one after another to the training data. Important to mention: We retrained all configurations from scratch. Experimental results are summarized in Figure 4. We report average BLEU scores grouped by the target language. We can see that adding training data $x \rightarrow y$ for a target language y, gives a significant boost in translation quality for that target language. These results demonstrate that even though we can translate between language pairs without seeing a single example during training, adding supervision during training significantly increases BLEU scores.

Adding a New Language We further investigate how a cMNMT model behaves when fine-tuned (Freitag and Al-Onaizan, 2016) to a new language. We chose Italian as the new language as the test set newstest2009 is multi-way in Czech, English, French, German, Italian and Spanish and thus we can report BLEU scores between all language pairs. We run two experiments with two different sets of fine-tuning data. First, we fine-tuned the cMNMT model (Table 9) on English↔Italian news-commentary (45,000 examples). Second, we converted the same data into multi-way aligned examples by augmenting the bilingual examples with translations into other languages when found in our

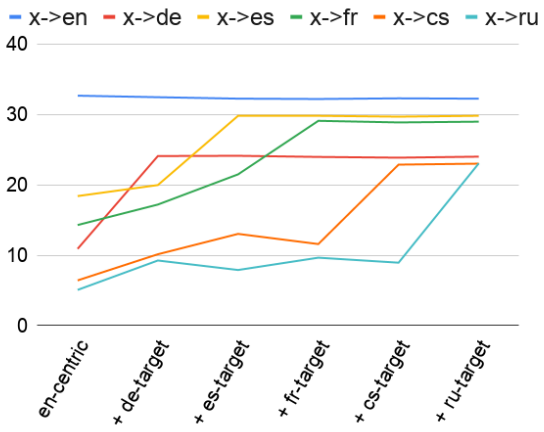

Figure 4: BLEU scores of models using only parts of the multi-way training data.

original training data. Experimental results for fine-tuning our model for one epoch on either of the two datasets can be found in Table 12. Both fine-tuning experiments show the same BLEU improvements for Italian↔English. Nevertheless, when only fine-tuning on English↔Italian data, we sacrifice translation quality for most of the language pairs which can be seen in the $x \rightarrow y$ column. Further, fine-tuning on multi-way aligned examples does improve the average BLEU scores by 4.3 BLEU for translations into Italian ($x \rightarrow$it). Overall, these experiments suggest that fine-tuning with multi-way aligned data is superior.

model	it→en	it→ x	en→it	$x \rightarrow$it	$x \rightarrow y$
cMNMT	13.5	9.7	2.3	2.6	22.0
+ft en↔it	21.5	14.2	13.6	11.8	17.8
+ft mway	21.2	18.5	13.5	11.9	23.0

Table 12: BLEU scores for newstest2009 for fine-tuning (ft) our cMNMT model on either English↔Italian (it↔en) news-commentary or on the same sentences but augmented with translations into other languages (mway), if available. Column $x \rightarrow y$ shows average BLEU scores for all language pairs.

Scaling cMNMT: 12,432 Language Pairs We run additional experiments on a 112 language in-house dataset (Arivazhagan et al., 2019b) to see if our approach scales to 12,432 language pairs. Our in-house dataset does not only contain more languages than the WMT setup, but also has a much wider range of available training resources. While for the high resource languages, we have access to billions of training examples, most of the low resource languages have less than 1 million training examples. We refer the reader to the description in Arivazhagan et al. (2019b) for more details regarding the dataset. Figure 5 shows the training data sizes and the average translations per multi-way example.

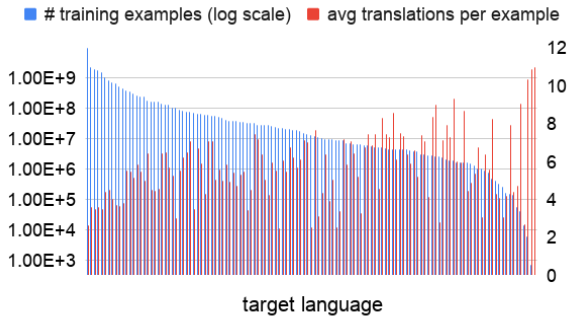

Figure 5: Average translations per multi-way example conditioned on the target language.

Although a deeper and wider architecture does improve the quality of multilingual models for this dataset, we use the same experimental setup as used in our WMT experiments (see Section 4) to run an MNMT and cMNMT model on our in-house data. Experimental results can be seen in Table 13. cMNMT outperforms MNMT for non-English languages by 10.1 BLEU points on average while keeping the translation quality for language pairs that include English as source or target. These results demonstrate that our proposed approach does scale far behind the six language WMT setup.

	en→ x	$x \rightarrow$en	$x \rightarrow y$
all	+0.34	-0.05	+10.1
low resource	+0.23	-0.15	+8.82
mid resource	+0.35	-0.05	+11.02
high resource	+0.45	+0.04	+9.73

6 Related Work

Direct models To translate between languages with little training data, three general approaches emerged, i. bridging through a third language (pivot-based MT) (Cheng et al., 2016; Currey and Heafield, 2019), ii. generating pseudo-parallel data between direct language pairs and training the direct pairs with that (zero-resource MT) (Firat et al., 2016b; Chen et al., 2017) and, iii. zero-shot methods where the model is asked to translate a direct pair only at test time (Johnson et al., 2017; Ha et al., 2016; Arivazhagan et al., 2019a).

Although pivot-based approaches perform sufficiently good when cascaded with strong bilingual models (Gu et al., 2019), their practicality is limited due to compounding errors from pipelining and doubled inference cost. The zero-resource approaches, combined with iterative-back translation (Hoang et al., 2018) are quite powerful but their inefficiency is worth noting. For N languages, one needs to devise a training routine that could sample $N^2 - N$ pairs, generate pseudo-parallel data. The added time to generate pseudo-parallel data for every pair grows quadratically, making it challenging for systems considering a large number of languages. Recently, by devising a practical sub-sampling approach, (Zhang et al., 2020) demonstrated zero-resource techniques could be scaled to massively multilingual setup. We find the study by (Zhang et al., 2020) closest to our work, having the goal of any-to-any multilingual translation. But compared to sampling language pairs with no parallel data and generating pseudo-parallel data on-the-fly, our approach makes use of existing multi-way alignment information before training. Lastly, zero-shot approaches attempt to measure the generalization performance of the MNMT models, but to date, the zero-shot quality still trails behind the pivot and zero-resource methods (Al-Shedivat and Parikh, 2019). Our proposed cMNMT, naturally fills the gap between these three approaches, the multi-way data can be extracted offline, and efficiently be mixed with the original data using a hierarchical data sampler. It does not require extra steps to generate pseudo-parallel data, and (as expected) it handily outperforms zero-shot approaches.

N-way data In this paper, we only made use of multi-way aligned data to sample bilingual pairs out of it. But there exist several approaches that make use of the multi-view structure in the data, such as Dabre et al. (2019), who explored the use of small multi-parallel corpora a for one-to-many NMT. Another approach is multi-source NMT (Zoph and Knight, 2016). Although multi-source NMT is a promising direction, it has practical problems such as lacking multiple sources at inference time (Nishimura et al., 2018). We believe research in this direction will be the key to improve mid/high-resource NMT and address several robustness issues to the input noise. Aulamo et al. (2020) recently released MultiParaCrawl where the authors extracted direct data for non-English language pairs from the English-centric Paracrawl corpus.

Sampling scheduling Several approaches proposed to address data sampling for multi-task models, some relying on temperature-based heuristics (Lee et al., 2016; Devlin et al., 2018; Arivazhagan et al., 2019b), others relying on adaptive schedules that incorporate the model gains, baselines or quality expectations into the data schedulers (Kiperwasser and Ballesteros, 2018; Jean et al., 2019; Wang et al., 2020). We believe data sampling is a critical research area for not only MNMT but also multi-task learning in general. We reveal a critical failure mode of the commonly used temperature sampling strategy, and how it causes the poor translation quality while translating out of English.

7 Conclusion

In this work, we introduced complete Multilingual Neural Machine Translation (cMNMT) that exploits the multi-way alignment information in the underlying training data to improve translation quality for language pairs where training data is scared or not available. Standard MNMT models are trained on a joint set of different training corpora for a variety of language pairs. cMNMT combines the different corpora and constructs multi-way aligned training examples that consist of translations of the same sentence into multiple languages. In combination with a novel temperature-based sampling approach that is conditioned on the target language only, we show that cMNMT is superior to the standard MNMT model and the even better-performing bridging approach. Experimental results on a public WMT 30 language pairs dataset and an in-house 12,432 language pairs dataset demonstrated an average BLEU increase of more than 10 BLEU points for non-English language pairs. This approach leads to a single NMT model that can serve 12,432k language pairs with reasonable quality which also surpasses the translation quality of the bridging approach, which is nowadays used in most modern MT services.

Paraphrase Generation as Zero-Shot Multilingual Translation: Disentangling Semantic Similarity from Lexical and Syntactic Diversity

Brian Thompson
Johns Hopkins University
brian.thompson@jhu.edu

Matt Post
Johns Hopkins University
post@cs.jhu.edu

Abstract

Recent work has shown that a multilingual neural machine translation (NMT) model can be used to judge how well a sentence paraphrases another sentence in the same language (Thompson and Post, 2020); however, attempting to *generate* paraphrases from such a model using standard beam search produces trivial copies or near copies. We introduce a simple paraphrase generation algorithm which discourages the production of n-grams that are present in the input. Our approach enables paraphrase generation in many languages from a single multilingual NMT model. Furthermore, the amount of lexical diversity between the input and output can be controlled at generation time. We conduct a human evaluation to compare our method to a paraphraser trained on the large English synthetic paraphrase database ParaBank 2 (Hu et al., 2019c) and find that our method produces paraphrases that better preserve meaning and are more gramatical, for the same level of lexical diversity. Additional smaller human assessments demonstrate our approach also works in two non-English languages.

1 Introduction

Paraphrase generation is the task of producing a fluent output sentence which is semantically similar to the input sentence while being syntactically and/or lexically different from it (Bhagat and Hovy, 2013). Paraphrasing has been of longstanding interest in the NLP community (McKeown, 1983) and has been used for data augmentation in question answering (Dong et al., 2017; Gan and Ng, 2019), machine translation (MT) (Hu et al., 2019a; Khayrallah et al., 2020), task oriented dialog (Niu and Bansal, 2018, 2019), and MT metrics (Banerjee and Lavie, 2005; Zhou et al., 2006; Denkowski and Lavie, 2010; Thompson and Post, 2020).

Thompson and Post (2020) recently released the Prism MT metric, which uses a multilingual neural MT (NMT) model as a paraphraser to *score* paraphrastic pairs; they treat paraphrasing as a zero-shot translation task (e.g., "translation" from English to English) and force-decode and score MT system outputs conditioned on their respective human translations. They denote their paraphraser as *lexically/syntactically unbiased* as it does *not* prefer output that differs lexically or syntactically from the input; this is advantageous for an MT metric as it assigns the highest score to an MT output which matches or nearly matches a human reference, but generating from the Prism model using standard beam search produces trivial copies or near copies.

We introduce a simple method to enable paraphrase generation from a multilingual NMT model.[1] Our method discourages the model from producing n-grams that match n-grams in the input sentence. This serves to lexically bias the output away from the input sentence, resulting in non-trivial paraphrases.

When considered together with Prism model of Thompson and Post (2020), our paraphrase generation approach offers several potential advantages over the common technique of training a paraphrase model on synthetic paraphrases generated by translating one side of bitext into the language of the other side (Wieting et al., 2017; Wieting and Gimpel, 2018; Hu et al., 2019c):

- The fluency/semantic similarity vs lexical diversity trade-off can be controlled at generation time.
- The approach works in many languages, with a single model.
- The approach addresses an inherent shortcoming in creating synthetic paraphrases from bi-

Proceedings of the 5th Conference on Machine Translation (WMT), pages 561–570
Online, November 19–20, 2020.

text in which ambiguities in one language can create errorful synthetic paraphrases in the other (see §6).

- Separating the fluency and semantic similarity model from the lexical and/or syntactic diversity model allows them to be developed and evaluated with less interdependencies.

We conduct human evaluations to compare our proposed method to a strong English baseline paraphraser trained on the ParaBank 2 dataset (Hu et al., 2019c), which consists of 50 million synthetic examples generated by translating the Czech side of Czech–English bitext into English and pairing it with the original English. We find that our method outperforms this baseline—both in terms of semantic similarity and grammaticality—when our system is adjusted to match the lexical diversity of the baseline. We also present small scale evaluations that suggest our method is effective in other languages.

2 Related Work

Paraphrase Generation Machine translation techniques can be used to train paraphrase models (Quirk et al., 2004). Another method to generate a paraphrase is to translate a text to a different language and then back again (Mallinson et al., 2017). Multiple pivot languages can be used to lessen the effect of inherent ambiguities (Aziz and Specia, 2013), at the expense of complication. Several works have focused on training on paraphrase data, including synthetic data created by starting with bitext and translating one side into the language of the other side to create synthetic paraphrases (Wieting et al., 2017; Wieting and Gimpel, 2018; Hu et al., 2019c). Ideas such as adversarial training (Iyyer et al., 2018), reinforcement learning (Li et al., 2018), and variational autoencoders (Gupta et al., 2018; Chen et al., 2019b) have also been explored in the context of paraphrase generation.

Diversity in Generation Creating paraphrases which differ from their input in non-trivial ways is a challenging problem. Hu et al. (2019c) used constrained decoding (Hokamp and Liu, 2017) in conjunction with a set of constraints (e.g., avoiding certain words which are present in the input) when creating synthetic paraphrases from bitext. Kajiwara (2019) also used hard constraints, but at decoding time. Our work is similar but uses "soft" constraints (i.e., down-weighting tokens which complete n-grams in the input, but not disallowing them all together). Another approach is to control generation with syntactic examples (Iyyer et al., 2018; Chen et al., 2019a) or codes (Shu et al., 2019).

Multilingual NMT Multilingual NMT (Dong et al., 2015) has been shown to enable zero-shot translation—that is, translation between languages pairs not included in training (e.g., translating from Spanish→Arabic at test time when the model was trained on Spanish→English and English→Arabic, but not Spanish→Arabic) (Johnson et al., 2017; Gu et al., 2018; Pham et al., 2019). Zhou et al. (2019) also explored incorporating paraphrase data into training to improve multilingual NMT performance.

Tiedemann and Scherrer (2019) explored using paraphrase recognition to test the semantic abstraction of a fairly small multilingual NMT system trained on Bibles and also demonstrate the model's ability to paraphrase in English. However, they did not perform a human evaluation of paraphrase quality, and Thompson and Post (2020) found that simply generating via beam search from a multilingual NMT model trained on a large general domain corpus results in trivial copies most of the time. We build upon Tiedemann and Scherrer (2019) by using a larger, general domain model, introducing a novel generation algorithm to produce output with lexical diversity, and performing human evaluations.

Paraphrastic similarity Similarity between intermediate representations produced by multilingual NMT encoders has been used to measure semantic similarity and/or paraphrastic similarity (Schwenk and Douze, 2017; Wieting et al., 2019; Raganato et al., 2019). Similarly, Prism (Thompson and Post, 2020) use a multilingual NMT model as a lexically/syntactically unbiased paraphraser for scoring MT system outputs conditioned on their associated human reference translations. We build on this by introducing a lexical bias away from the input at generation time, enabling the use of a multilingual NMT model as a generative paraphraser.

3 Method

Let x and y be sentences, let $\mathcal{M}(x)$ represent the meaning of x, and let $S(x, y)$ measure the lexical and/or syntactic similarity between the two sentences. Formally, we can state the problem of para-

Algorithm 1 Before paraphrasing a sentence, `buildPenalties()` is called to construct a mapping of word prefixes to subwords that require penalties. Then, `penalize()` is called to modify the model prediction `targetLogProbs` at every decoder timestep.

```
def buildPenalties(source):
  penalties = defaultdict(list)
  for n in [1, 2, 3, 4]:
    for ngram of size n in subwords2words(source):
      prefix, word = ngram[0:-1], ngram[-1]
      for subword in targetVocab:
        if word.lower().startsWith(subword.lower()):
          penalties[prefix].append(subword)
  return penalties

def penalize(history, penalties, targetLogProbs):
  for n in [1, 2, 3, 4]:
    prefix = subwords2words(history)[-(n-1):]
    for subword in penalties[prefix]:
      targetLogProbs[id(subword)] -= alpha * (n ** beta)
```

phrase generation as finding $\hat{y}$:

$$\hat{y} = \underset{y}{\operatorname{argmax}} \left[p(y \mid \mathcal{M}(x)) - \alpha S(x, y) \right] \quad (1)$$

where α controls the semantic similarity and fluency vs lexical and/or syntactic diversity trade-off.

3.1 Lexically/Syntactically Unbiased Paraphraser

The intralingual probability $p(y \mid \mathcal{M}(x))$ can be viewed as a lexically/syntactically unbiased paraphraser. This model is responsible for producing output which is both semantically similar to the input and fluent, but has no notion of lexical and/or syntactic diversity. We use the multilingual NMT system released with Prism to model $p(y \mid \mathcal{M}(x))$.

3.2 Lexical Bias

We choose n-gram overlap as our measure of lexical and/or syntactic similarity $S(x, y)$, and propose a simple n-gram overlap measure that penalizes the production of n-grams matching n-grams in the input sequence to enable the paraphrase generation. Our proposed algorithm begins by constructing a set of all (word) n-grams, $1 \leq n \leq 4$, from the input.[2] At each decoding step, the algorithm checks whether any of the target vocabulary subwords *begin* the last word of an input n-gram.[3] All such subwords are penalized by subtracting αn^{β} from the output log probabilities of the NMT model before selecting candidates to extend the beam, where n is the n-gram length, α is the user-specified trade-off between semantic similarity and lexical diversity, and β is another user-defined hyperparameter.

We experimented with penalizing 1-, 2-, 3-, and 4-grams equally but found it produced disfluent output, as the algorithm tended to avoid all words in the input. The exponential weight allows us to penalize the decoder for producing larger overlapping n-grams more harshly than small ones. All experiments in this work use $\beta = 4$, as this produced output in English which appeared fluent to the authors. Finally, the NMT model's vocabulary contains case variants (e.g., "his" and "His") and we do not want to add variation by trivially changing the case of words, so we penalize all case variants of the next tokens. Pseudocode for our approach is provided in Algorithm 1. Note that this method is much simpler than the method used to generate training data for ParaBank 2, which including hand-written constraints, scoring, filtering, and clustering.

[2] In this work, we assume words are separated by whitespace. For languages which do not denote word boundaries, our method could likely be applied after tokenizing the input, or by simply treating each SentencePiece token as a word.

[3] We apply the penalty at the start of the generation of the last word of an input n-gram so that the decoder is not encouraged to produce an unnatural completion to an already-begun word.

3.3 Diversity Control

The α parameter in Equation 1 provides the user with a knob to control how strongly the output is "pushed" away from the input, in lexical space, during generation. In contrast to positive and negative hard lexical lexical constraints (Hokamp and Liu, 2017; Post and Vilar, 2018; Hu et al., 2019c), our method requires no user-defined constraints, making it simpler and perhaps more language agnostic.[4]

3.4 Development and Evaluation

Paraphrase evaluation is complicated by the fact that many different aspects of paraphrases can be evaluated including semantic similarity between input and output, fluency, grammatical correctness, lexical diversity between input and output, and syntactic diversity between input and output. The relative importance of these aspects is not intuitively obvious and is likely determined by downstream tasks.

Modeling semantic similarity and lexical/syntactic diversity separately has the potential to somewhat lessen the burden of evaluation in several ways:

1. There are several potential ways to automatically evaluate the model $p(y \mid \mathcal{M}(x))$. One option is to evaluate perplexity on a test set consisting of human paraphrases. (Thompson and Post (2020) found that their multilingual NMT model assigned higher probability to both copies of the input and human paraphrases of the input, compared to a model trained on ParaBank 2.) Another option is to test models of $p(y \mid \mathcal{M}(x))$ on pairs of paraphrases where one paraphrase has been deemed to better preserve the semantic meaning of the input. Such datasets already exist, in about a dozen languages, due to the annotation efforts undertaken at the annual WMT evaluations.[5] In other words, we can simply treat a model of $p(y \mid \mathcal{M}(x))$ as an MT metric in order to judge its quality. In other words, we can simply treat a model of $p(y \mid \mathcal{M}(x))$ as an MT metric in order to judge its quality.
2. By applying the lexical/syntactic bias in generation, development of the generation algorithm can be conducted without the time/cost of re-training a model, and multiple generation schemes can be directly compared using the same $p(y \mid \mathcal{M}(x))$ model, such as the freely available Prism model (Thompson and Post, 2020).
3. Being able to control the amount of lexical and/or syntactic diversity at inference time allows for easier comparison with prior paraphrasing work, as the diversity can be adjusted to match that of a prior method. (We employ this approach in §4.3.1.)

4 Experimental Setup

4.1 Primary Model

We use the multilingual NMT model released with Prism (Thompson and Post, 2020), which uses a Transformer (Vaswani et al., 2017) architecture with approximately 750 million parameters. The model was trained in fairseq (Ott et al., 2019). The authors take several steps to encourage the encoder and decoder to be language agnostic, including specifying the target language as the first token in the target, so that the encoder does not know the target language, and training on several datasets that include a large number of different language pairs. The model was trained on several open source datasets including WikiMatrix (Schwenk et al., 2019), Global Voices,[6] EuroParl (Koehn, 2005) SETimes,[7] and United Nations. After filtering, this resulted in approximately 100 million translation pairs and covering 39 languages. The model uses a shared, multilingual vocabulary of 64k SentencePiece tokens (Kudo and Richardson, 2018).

4.2 Baseline Model

As a baseline, we train an English-only paraphraser in fairseq on the ParaBank 2 dataset (Hu et al., 2019c) with approximately 253M parameters and a SentencePiece vocabulary of 16k tokens. We train a Transformer with an 8-layer encoder, 8-layer decoder, 1024 dimensional embeddings, embedding sizes of 1024, feed-forward size of 4096, and 16 attention heads. Dropout is set to 0.3, label smooth-

[4] One concern with hard constraints is that there are sometimes words or phrases (e.g., proper nouns) that should not be paraphrased, as doing so would change the meaning of the sentence. Thus heuristics are often used to determine which words/phrases should be constrained.

[5] In particular, the relative ranking judgements collected through 2016 (Bojar et al., 2016) are probably the most relevant.

ing to 0.1, and learning rate to 0.0005, and batch size was 31200 tokens. Other parameters match the fairseq defaults. The model trained for approximately 6 weeks (33 epochs) on 4 Nvidia 2080 GPUs.

4.3 Evaluation

We conduct a manual evaluation in English using Mechanical Turk workers and conduct smaller scale manual evaluations in German and Spanish, with the help of colleagues who are native speakers. We perform human evaluations following (Hu et al., 2019b), described in more detail below.

4.3.1 English Evaluation

In this work, we focus on evaluation of semantic similarity, grammatical correctness, and lexical diversity. For the model trained on ParaBank 2, the trade-off between these dimensions is fixed and built into the model. To make a fair comparison, we adjust our overlap penalty (α) such that the output of our method matches the lexical diversity of the model trained on ParaBank 2. Following Hu et al. (2019c), we use uncased BLEU (Papineni et al., 2002), computed between input and output, to estimate the lexical diversity of the paraphraser.

We evaluate in English using Mechanical Turk workers who were selected from a curated list of previously vetted workers. Annotators were presented with a reference sentence and four paraphrases: three paraphrases from our proposed method (at three different operating points) and one from the model trained on ParaBank 2, presented in random order. For each paraphrase, the annotators were asked to (1) rate the paraphrase as (i) grammatical, (ii) having one or two small grammatical errors, or (iii) ungrammatical, and (2) rate the semantic similarity between the input and the paraphrase using an analog slider bar from 1–100. We randomly select 200 sentences from the English side of the WMT19 German–English test set (Barrault et al., 2019) and obtain ratings from three annotators, for each sentence at each paraphrase system/setting combination. Annotators were paid 0.50 USD per HIT.

For our proposed method, we choose three operating points: $\alpha = 0.0005$, α=0.003, and α=0.006 (Figure 1). The middle point of α=0.003 was chosen so as to produce output with the same lexical diversity as the paraphraser trained on ParaBank 2, as described above. We decode with a beam size of 5, using the fairseq defaults.

4.3.2 German & Spanish Evaluation

We also collect human judgments in German and Spanish. We follow the evaluation procedure described above for the English paraphraser except that annotations were done by colleagues who were native speakers in these languages. For Spanish, we used the target side of the WMT 2013 English–Spanish test set (Bojar et al., 2013). For German, we used the target side of the WMT 2019 English–German test set (Barrault et al., 2019). We obtained 50 judgments per set of 3 paraphrases by one German annotator, and 150 judgments per set of 3 paraphrases by three Spanish annotators, both on a random sample of sentences. Multiple paraphrases from our proposed method at different operating points (i.e., different values of α) were shown to the annotator, in random order.

5 Results

5.1 English Results

Human evaluation results in English are shown in Figure 2. We find that α is negatively correlated with grammaticality and semantic similarity between the input and output and positively correlated with lexical diversity of the output with respect to the input, as expected.

We find that at the operating point $\alpha = 0.003$, which was chosen such that our method has the same lexical diversity as the model trained on ParaBank 2, the paraphrases from our method were judged to be both more semantically similar to the input and grammatical (slightly) more often.

5.2 German & Spanish Results

The human evaluation results in German and Spanish, along with English for reference, are shown

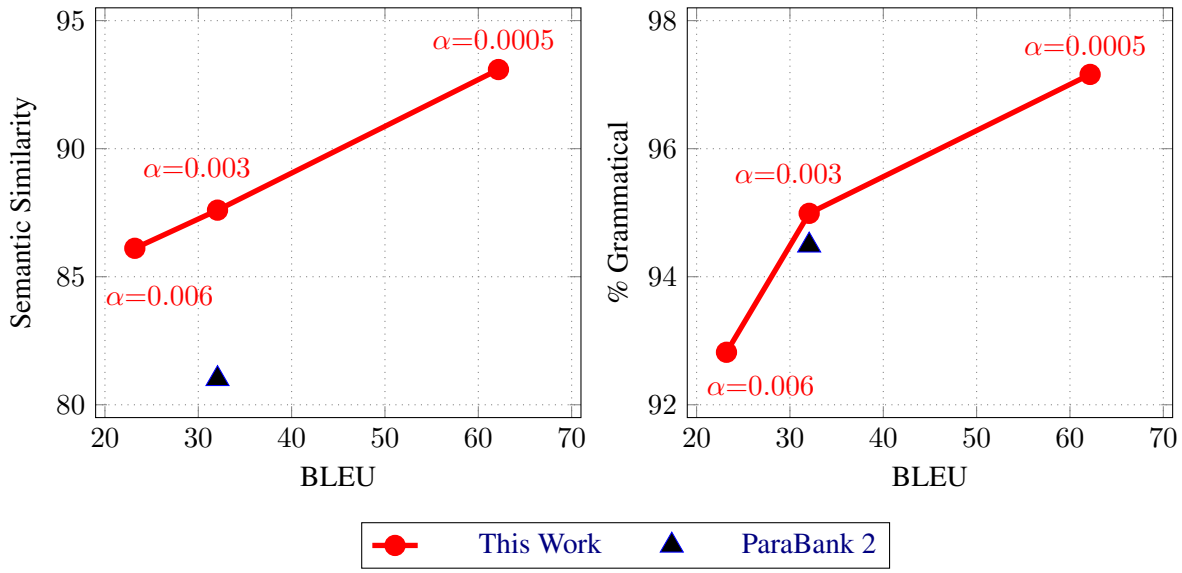

Figure 2: Human judgments of English paraphrases for semantic similarity (rated 1–100) and the percentage of sentences produced which were rated as grammatical, both as a function of lexical/syntactic diversity (measured via uncased BLEU between input and output). We evaluated our generation method at three operating points (α=0.0005, α=0.003, and α=0.006). α=0.003 was chosen to match such that the proposed method had the same diversity as the model trained on Paracrawl2. At that operating point, humans rated output of our method to be more semantically similar to the reference (87.5 vs. 81.0), and grammatical slightly more often (95.0% vs. 94.5%).

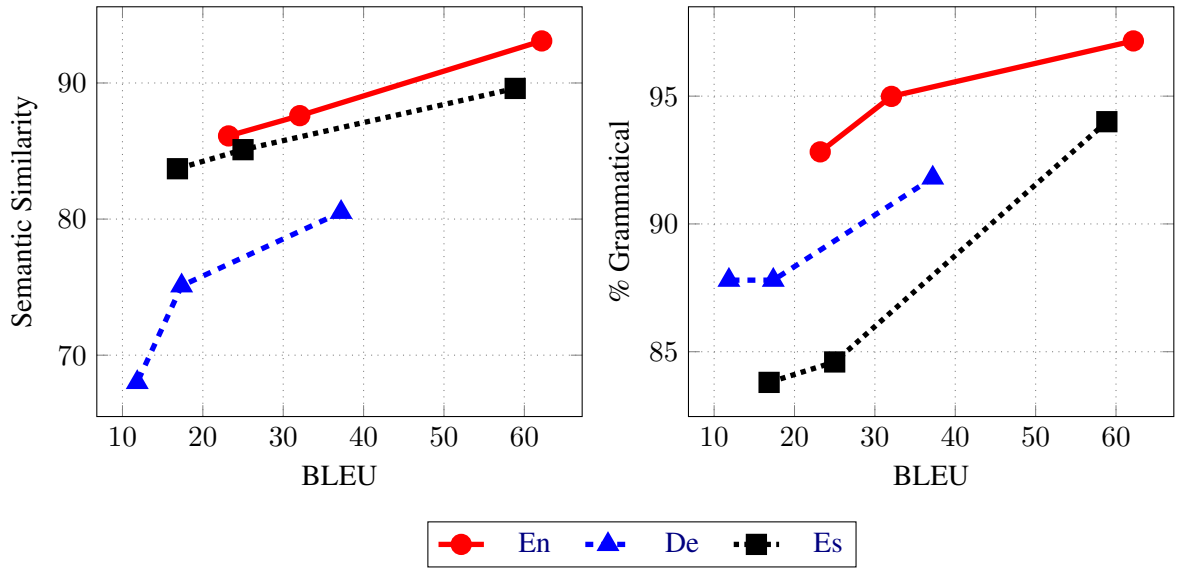

Figure 3: Human judgments of German (De) and Spanish (Es) paraphrases, with English (En) shown for reference, plotted against uncased BLEU computed between the paraphraser input and output. The judgement criteria and α values match English settings. α decreases from left to right in all plots.

in Figure 3. Note that we have no way to normalize between annotators in different languages, thus the results should *not* be used to draw conclusions about the *relative* performance of the paraphraser of these languages. However, we find the trends are similar across all three languages, and that semantic similarity and grammaticality judgements for Spanish and German are both reasonably high.

6 Discussion

We hypothesize that our method outperforms the baseline because it does not suffer from a fundamental shortcoming in creating synthetic paraphrase data from bitext: namely that inherent ambiguities present in one language (but not the other) can cause erroneous synthetic paraphrases in the

other language (Aziz and Specia, 2013).

For the sake of discussion we consider gender[8] as an ambiguity. Suppose we create synthetic English paraphrases from Turkish–English data, and our bitext contains the following (valid) sentence pair: ("O mağazaya gitti.", "She went to the store.") Turkish is a gender-neutral language, so when we translate the Turkish side to English it is perfectly valid to translate the sentence to "He went to the store." Pairing the original English translation with the translation results in the synthetic paraphrase example ("She went to the store.", "He went to the store."). Since English is gendered, this results in an invalid synthetic paraphrase.

In contrast, consider what happens if "She went to the store." is paraphrased by our method. First, the sentence is converted to an intermediate representation by the encoder. If the encoder were from an English→Turkish system, it is plausible that the encoder would discard gender information, as it is not needed in the target language. However, our encoder comes from a multilingual system which can produce output in *many* different languages. Thus, as long as the model has seen a sufficient number of training examples between English and at least one other gendered language, we can reasonably expect that the intermediate representation will preserve gender. Thus, when this representation is passed to the decoder and English is requested as the target language, the model should put low probability on any output for which the subject is male.

An alternative way to address pivot language ambiguities is to use multiple pivot languages, as proposed by Aziz and Specia (2013). However, it is not clear how best to extend this idea to neural sequence-to-sequence models, or to a multilingual paraphraser. Combining synthetic paraphrases for training using several different pivot languages would mitigate the errors due to ambiguities from any one pivot language, at the expense of errors due to ambiguities in other pivot languages. To really address such errors would require combining models of different language pairs; see Mallinson et al. (2017) for one such solution.

7 Conclusions

We treat paraphrasing as a zero-shot translation task and present a method to control the lexical diversity of paraphrases generated from a multilingual NMT model, enabling paraphrase generation in many languages. Our approach gives a user fine-grained control over the amount of lexical diversity at generation time, and also allows models and generation algorithms to be developed and evaluated with less interdependencies. There are likely many other ways that the output could be controlled to vary other aspects, such as syntactic diversity (Shu et al., 2019); we would like to explore such methods in future work.

Our work outperforms an English baseline trained on a large synthetic paraphrase dataset (Hu et al., 2019b). This improvement in performance may be because our method does not suffer from the issue that ambiguities in the pivot language used to create synthetic paraphrase data can cause errors in synthetic data. Small experiments indicate our method also performs well in other languages.

Multilingual NMT is an active research area and we are optimistic that this approach will pave the way for even stronger paraphrase generation in the future, as multilingual NMT methods continue to improve and models are publicly released.

Acknowledgments

The authors wish to thank Ben Van Durme for helpful technical discussions, and Carlos Aguirre, Sabrina Mielke, Rachel Wicks, and others for assistance with annotations.

[8] Czech is, of course, gendered, so we would not expect the ParaBank 2 dataset (which was created from Czech–English bitext) to have gender errors. But the logic presented here should generalize to other ambiguities.

When Does Unsupervised Machine Translation Work?

Kelly Marchisio and **Kevin Duh** and **Philipp Koehn**

Abstract

Despite the reported success of unsupervised machine translation, the field has yet to examine the conditions under which the methods succeed and fail. We conduct an extensive empirical evaluation using dissimilar language pairs, dissimilar domains, and diverse datasets. We find that performance rapidly deteriorates when source and target corpora are from different domains, and that stochasticity during embedding training can dramatically affect downstream results. We advocate for extensive empirical evaluation of unsupervised MT systems to highlight failure points and encourage continued research on the most promising paradigms. Towards this goal, we release our preprocessed dataset to stress-test systems under multiple data conditions.

1 Introduction

Machine translation (MT) has progressed rapidly since the advent of neural machine translation (NMT) (Kalchbrenner and Blunsom, 2013; Bahdanau et al., 2015; Sutskever et al., 2014) and is better than ever for languages for which ample high-quality bitext exists. Conversely, MT for low-resource languages remains a great challenge due to a dearth of parallel training corpora and poor quality bitext from esoteric domains. To address this, several authors have proposed unsupervised MT techniques, which rely only on monolingual text for training (e.g., Ravi and Knight, 2011; Yang et al., 2018; Artetxe et al., 2018c; Hoshen and Wolf, 2018; Lample et al., 2018a,b; Artetxe et al., 2018b, 2019).

Recent unsupervised MT results appear promising, but they primarily report results for the high-resource languages for which traditional MT already works well. The limits of these methods are so far under-explored. For unsupervised MT to be a viable path for low-resource machine translation, the field must determine (1) if it works outside highly-controlled environments, and (2) how to effectively evaluate newly-proposed training paradigms to pursue those which are promising for real-world low-resource scenarios. Unsupervised MT methods must work (1) on **different scripts** and between **dissimilar languages**, (2) with **imperfect domain alignment** between source and target corpora, (3) with a **domain mismatch** between training data and the test set, and (4) on the low-quality data of **real low-resource languages**. These factors reflect the real-life challenges of low-resource translation.

Our main contribution is an extensive analysis of unsupervised MT with regards to factors (1)-(3) above.[1] We find that (a) translation performance rapidly deteriorates when source and target corpora are from different domains, (b) stochasticity during word embedding training can dramatically affect downstream bilingual lexicon induction (BLI) and translation performance, and (c) like in the bilingual lexicon induction literature, unsupervised MT performance declines when source and target languages are dissimilar. While (4) is not the focus of this paper, we do observe very low performance on an authentic low-resource language pair, corroborating previous studies (Guzmán et al., 2019).

Finally, as there are no standard evaluation protocols to ensure that unsupervised MT systems are robust to the types of data anomalies ubiquitous in low-resource translation settings, we advocate for extensive empirical evaluation of unsupervised MT systems to highlight failure points and encourage continued research on the most promising paradigms.

We first discuss related work in Section 2, followed by a detailed overview of the unsupervised MT architecture in Section 3. In Section 4, we discuss our research questions, followed by our evaluation methodology and datasets in Sections 5

[1] We release our full dataset at http://statmt.org/when-does-unsup-work to facilitate the stress-testing of systems.

Proceedings of the 5th Conference on Machine Translation (WMT), pages 571–583
Online, November 19–20, 2020.

and 6. Section 7 presents our findings, and Section 8 discusses the results. We conclude in Section 9.

2 Related Work

Bilingual Lexicon Induction Unsupervised MT methods can be thought of as an end-to-end extension of work inducing bilingual lexicons from monolingual corpora. Bilingual lexicon induction (BLI) using non-parallel data has a rich history, beginning with corpus statistic and decipherment methods (e.g., Rapp, 1995; Fung, 1995; Koehn and Knight, 2000, 2002; Haghighi et al., 2008), continuing to modern neural methods to create crosslingual word embeddings (e.g. Mikolov et al., 2013a; Conneau et al., 2018, see Ruder et al. (2019) for a survey) which form a critical component of state-of-the-art unsupervised MT systems.

Evaluation of Embedding Spaces Søgaard et al. (2018) determine that monolingual embedding spaces of similar languages are not typically isomorphic as was previously believed, and that bilingual dictionary induction "depends heavily on... the language pair, the comparability of the monolingual corpora, and the parameters of the word embedding algorithms." Vulić et al. (2019) argue that unsupervised approaches are unsuccessful with dissimilar languages and domains, and that unsupervised performance has been overly lauded because the conditions under which they were compared with supervised baselines were inequitable.

While a modest body of literature has examined the quality of cross-lingual word embeddings (CLEs) by measuring performance on BLI, Glavaš et al. (2019) evaluate on downstream natural language tasks, underlining the importance of full-system evaluation. The authors conclude that "the quality of CLE models is largely task-dependent and that overfitting the models to the BLI task can result in deteriorated performance in downstream tasks." Similarly, Doval et al. (2019) investigate cross-lingual natural language inference.

Evaluation of Unsupervised MT Liu et al. (2020) helpfully re-define unsupervised machine translation into three distinct categories: (1) no bitext whatsoever, (2) the target language pair is linked through bitext via a pivot language, and (3) no linkage through a pivot language, but bitexts exists for *some* language and the target language. The authors analyze their multilingual pretraining method with respect to other similar training paradigms (Conneau and Lample, 2019; Song et al., 2019) and evaluate unsupervised MT performance when using backtranslation (Definition 1) or language transfer after finetuning on related bitext (Definition 3).

In unsupervised MT with no bitext, Lample et al. (2018b) ablate their PBSMT system, finding that initial phrase table quality is critical and that performance suffers when the language model is trained with less data. They tweak their NMT embedding initialization method, such as using separately-trained BPE instead of joint, and word embeddings instead of BPE token embeddings. They report the results of dropping part of their loss function and making minor changes to the NMT architecture on downstream BLEU score. Concurrently to our work, Kim et al. (2020) arrived at similar conclusions to us using a different autoencoder/dual-learning unsupervised MT approach based on cross-lingual language model pretraining (Conneau and Lample, 2019); this complements our experiments and corroborates our results.

3 Background: Unsupervised MT

Our experiments employ the models of Artetxe et al. (2018b, 2019) as representative of state-of-the-art for the class of unsupervised MT methods that bootstrap from cross-lingual word embeddings. Recent work such as Lample et al. (2018b) is based on similar concepts. For our purposes, unsupervised MT follows Liu et al. (2020)'s Definition (1) from Section 2, where no bitext exists.

Another approach to unsupervised MT involves pretraining a bilingual or multilingual model on monolingual text on a general task before finetuning on translation. Such methods include cross-lingual language model pretraining (Conneau and Lample, 2019), masked sequence-to-sequence pretraining (Song et al., 2019), and multilingual denoising pretraining (Liu et al., 2020), and have shown promise. For instance, Liu et al. (2020) record the first good results on the low-resource Sinhala-English and Nepali-English pairs. While pretraining and multilingual methods are not the subject of this work, they warrant future evaluation.

Figure 1 depicts the basic training process. It is the publicly-available SMT setup of Artetxe et al. (2018b)[2], plus the "NMT hybridization" steps from Artetxe et al. (2019).[3]

[2] https://github.com/artetxem/monoses

[3] Shared with us by Mikel Artetxe.

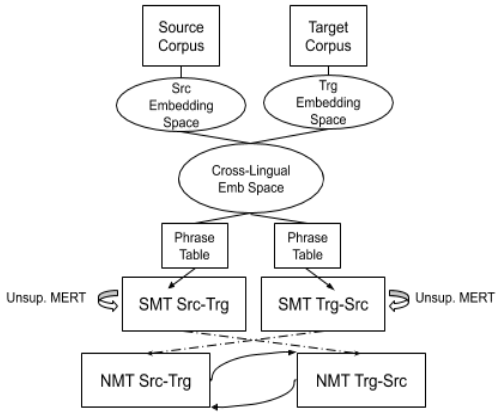

Figure 1: The unsupervised MT architecture used in this work. This model is a replication of Artetxe et al. (2018b) [steps before NMT] and Artetxe et al. (2019) [NMT component].

Training begins with two monolingual corpora which are not necessarily related in any way (i.e. they are not assumed to be parallel nor comparable text). First, word embeddings are trained independently for each corpus, resulting in a source and a target embedding space. Specifically, after preprocessing, Artetxe et al. (2018b) train two statistical language models using KenLM (Heafield, 2011), one for the source language and one for the target. They use phrase2vec[4] (Artetxe et al., 2018b), an extension of Mikolov et al. (2013b)'s skip-gram model,[5] to generate phrase embeddings for 200,000 unigrams, 400,000 bigrams, and 400,000 trigrams.

Next, source and target word embeddings are aligned into a common cross-lingual embedding space. They run VecMap[6] (Artetxe et al., 2018a) which calculates a linear mapping of one space to another based on the intuition that phrases with similar meaning should have similar neighbors regardless of language. Given a matrix of source word embeddings X and target word embeddings Z which have been length-normalized, mean-centered, then length-normalized again, VecMap calculates $M_x = XX^T$ and $M_z = ZZ^T$. Each cell $M_{x_{ij}}$ and $M_{z_{ij}}$ is the cosine similarity between words X_i and X_j, and Z_i and Z_j, respectively. M_x and M_z are symmetric, and if the monolingual vector spaces were fully isometric, M_x and M_z would be identical besides rows and columns being permuted. Each row of M_x and M_z is a similarity distribution. To exploit this, each row of $\sqrt{M_x}$ and $\sqrt{M_z}$ is sorted (they find that using the square root works better empirically), and length-normalized, mean-centered, and length-normalized again. For each row i in $sorted(\sqrt{M_x})$, they find the row j of $sorted(\sqrt{M_z})$ that is its nearest neighbor, and assign $X_i = Z_j$ in the initial translation dictionary D. A cell $D_{ij} = 1$ if words X_i, and Z_j are translations of one another, and 0 otherwise.

Next, there is an iterative process of calculating the optimal linear mappings and extracting an updated dictionary. For calculating the mapping, the goal is to find the linear transformations W_x and W_z which maximize the cosine similarity of the words that are translations of one another as defined by the dictionary D, over the entire dictionary:

$$\arg\max_{W_x,W_z} \sum_i \sum_j (D_{ij})((X_i W_x) \cdot (Z_j W_z))$$

From there, they calculate $M = XW_x W_z^T Z^T$, whereby each cell in M is the cosine similarity of word X_i and Z_j after their transformations with W_x and W_z. To avoid poor local optima, they stochastically zero-out some cells of M with probability $p = 0.9$, decreasing over time.

The final score for each potential translation candidate is calculated using Cross-domain Similarity Local Scaling (CSLS) (Conneau et al., 2018) to mitigate the hubness problem. CSLS utilizes cosine similarity, which is taken from M. For each pair of words X_i and Z_j, the new dictionary cell $D_{ij} = 1$ if the CSLS score between X_i and Z_j is the highest over all other words in Z, and $D_{ij} = 0$ otherwise. The dictionary is created in both directions, and concatenated. Readers are directed to Artetxe et al. (2018a) for further details.

The next step extracts an initial phrase-table for use in a SMT system. They use the softmax over the cosine similarity of the 100 nearest-neighbors of each source phrase embedding as the phrase translation probabilities. This is done in both directions:

$$(f|e) = \frac{e^{(\cos(e,f)/\tau)}}{\sum_{f'} e^{(\cos(e,f')/\tau)}}$$

For the target embedding with the highest cosine similarity, the phrases are aligned, and unigram translation probabilities are multiplied to become the lexical weighting.

Combining the preliminary phrase table with a distortion penalty and language model produces the initial unsupervised phrase-based SMT system (Koehn et al., 2007). The SMT model weights

[4] https://github.com/artetxem/phrase2vec

[5] https://github.com/tmikolov/word2vec

[6] https://github.com/artetxem/vecmap

are tuned using a variant of MERT (Och, 2003) designed for unsupervised scenarios, which uses 10,000 parallel sentences generated via backtranslation (Sennrich et al., 2016a). The SMT model then undergoes three rounds of iterative backtranslation.

Artetxe et al. (2019) extend their 2018 work by adding a critical "NMT hybridization" final step, which achieves significant gains over SMT alone.[7] An NMT system is trained using backtranslated output from SMT for one epoch. On the next epoch, a small number of sentences are backtranslated with the newly-trained NMT system and concatenated with a slightly smaller fraction of SMT-generated bitext. The procedure continues for 30 epochs, gradually increasing the percentage of synthetic training data created by the NMT system until all of the training data is NMT-generated. The NMT system is trained for an additional 30 epochs of iterative backtranslation using data generated fully by the NMT system of the previous epoch. The test set is translated with beam search using an ensemble of models saved at every tenth epoch (six total), resulting in BLEU scores of 33.2 and 26.4 (SacreBLEU (Post, 2018)) on newstest2014 for French-English and German-English, respectively.

We run Artetxe et al. (2018b, 2019)'s implementation for our experiments. Specifically, neural models are Transformer-big (Vaswani et al., 2017) trained with fairseq (Ott et al., 2019) on one NVIDIA GeForce GTX 1080Ti GPU. Models use shared embeddings, the Adam optimizer with $\beta_1 = 0.9$, $\beta_2 = 0.98$ (Kingma and Ba, 2015), label smoothing, initial learning rate of 1e-07 warming up for 4000 steps to 5e-04 before decaying, and dropout (Srivastava et al., 2014) probability of 0.3. We set optimizer delay to 4 to simulate 4 GPUs.

To elucidate the performance gap due to the unsupervised architecture, we build a standard supervised NMT system using the same neural architecture described above. We train until performance on the development set ceases to improve for 10 epochs. To parallel the unsupervised setup, we translate the test set using an ensemble of 6 models; We perform ensemble selection by performance on a validation set, selecting the best-performing checkpoint along with 5 previous checkpoints.

[7] Readers are directed to Artetxe et al. (2019) for additional changes that resulted in sizable BLEU (Papineni et al., 2002) gains before the NMT phase.

4 Research Questions

Existing unsupervised translation methods work well on languages which are similar to each other, use the same Roman script, and have an ample amount of monolingual news data available (which matches the test set domain). Questions remain as to whether unsupervised methods will be useful on authentic low-resource settings where few or none of the aforementioned properties hold. Namely, does unsupervised MT work with:

- dissimilar languages?
- dissimilar source and target domains?
- diverse datasets?
- authentic low-resource language pairs?

Such questions reflect the reality of authentic low-resource translation, and are those which must be adequately resolved for unsupervised MT to be a viable alternative to traditional translation methods for the most difficult language pairs.

5 Evaluation of Unsupervised MT

We perform an extensive empirical evaluation of unsupervised MT. Our evaluation protocol stress-tests an unsupervised MT system under varying conditions to reveal its points of strength and failure. Systems should be judged on how well they perform: (1) on dissimilar languages, (2) on increasingly divergent domains between source and target corpora, (3) on diverse datasets, and (4) on authentic low-resource language pairs where data quality is typically low. Namely, we:

1. Choose 2 language pairs, at least one of which where the source and target languages utilize different scripts.
2. Choose 3 datasets of different domains, at least one of which is parallel bitext.
3. Perform at least one experiment for each language pair under each of the following data conditions:
   - Originally parallel
   - Not originally parallel
   - Different domain for source and target.
4. Choose 2 *true* low-resource language pairs.

5. Judge the system based on performance in all tested scenarios.

The data conditions above are designed measure how well a system performs in regards to the research questions of Section 4. Namely, success on a variety of languages with different scripts and linguistic structure indicates robustness to dissimilar languages; success on multiple datasets of different domains indicates that the system is not specifically designed for one domain at the expense of others, and performs well even when training and test data do not match perfectly; Step #3 evaluates performance on increasingly divergent domains between source and target data; and Step #4 is the *true* test—whether the system succeeds on authentic low-resource language pairs.

6 Datasets

Training datasets used in our reinvestigation of the unsupervised MT system presented in Artetxe et al. (2019) are shown in Table 1. We focus on Russian-English (Ru-En) and French-English (Fr-En) tasks and include as reference Sinhala-English (Si-En) and Nepali-English (Ne-En) as well. Following Section 5, we evaluate the same system under various ablated data setups:

- The "Supervised" condition is the standard MT training setup which uses parallel bitext.
- In the "Parallel" condition, an *unsupervised* MT system is trained on a corpus that was originally parallel (i.e. UN corpus), now being treated as two separate monolingual corpora.
- In contrast, the "Disjoint" setting splits data from a parallel corpus into two disjoint halves, using the first half of the source-side corpus and the second half of the target-side corpus.
- In the "Different Domain" (Diff. Dom.) setting, source and target monolingual corpora come from different domains. This is a realistic setting in low-resource scenarios, and is expected to be much more difficult than the "Disjoint" setting.
- "News crawl" (News) and "Common Crawl" (CC) settings determine whether the system can flexibly handle diverse datasets.

Specifics of the datasets used are described in subsequent subsections. Token counts presented in the subsections below are before preprocessing, whereas Table 1 reflects the data remaining after the preprocessing procedure of Artetxe et al. (2018b). We will release the preprocessed data splits for others to compare their results with ours.

Condition		Corpus	Src	Trg
Repro	Fr-En	News	694	1940
	En-Fr	News	1940	694
Supervised	Fr-En	UN: A	346	301
	Ru-En	UN: A	284	284
Parallel	Fr-En	UN: A	302	270
	Ru-En	UN: A	232	241
Disjoint	Fr-En	UN: A / B	302	255
	Ru-En	UN: A / B	232	236
Diff. Dom.	Fr-En	UN: A / CC	302	226
	Ru-En	UN: A / CC	232	226
News	Fr-En	News	116	105
	Ru-En	News	120	105
CC	Fr-En	CC	110	79
	Ru-En	CC	115	79

Table 1: Training data after preprocessing. UN = United Nations, CC = Common Crawl, News = News crawl. "Diff. Dom." uses UN on the source-side and CC on the target-side. "News" is a subset of 2007-08 for En, 2007-09 for Fr, and 2008-11 for Ru. "Repro" is the condition most similar to (Artetxe et al., 2018b, 2019). Src (M) and Trg (M) columns are the token counts, in millions. "Supervised" count is in BPE tokens. All others are token counts for SMT (pre-BPE).

6.1 United Nations

The United Nations Parallel Corpus (UN) (Ziemski et al., 2016) contains official United Nations documents from 1990-2014, human-translated into six languages. The first 10,000 lines of each dataset are held-out. The remaining lines are partitioned into training sets A & B. Training set A on the source side and A on the target side are paired to form the Parallel training set; Training set A on the source side and B on the target side are paired to form the Disjoint training set.

6.2 News Crawl

News crawl (News) consists of monolingual data crawled from news websites. Data for each year has been shuffled. Following Artetxe et al. (2018b), we concatenate News crawl 2007-13 for English and for French. For Russian, we concatenate News crawl 2008-18. We use the deduplicated Russian corpus. We use the full datasets to reproduce

Artetxe et al. (2018b, 2019)'s work. For subsequent experiments, we use a subset: the first 100 million tokens from each concatenated News crawl corpus before preprocessing. For English, this is all of News crawl 2007 and ∼23.3 million tokens from News crawl 2008. For French, it is News crawl 2007, 2008, and some of 2009. For Russian, it is News crawl 2008-2010, and some of 2011.

6.3 Common Crawl

The Common Crawl (CC) corpora consists of web-scraped monolingual data ordered as documents. We extract two training datasets from the English corpus - one with the first ∼291 million tokens and another with the first ∼100 million for Diff. Dom and CC experiments, respectively. We do not shuffle this data, as having less documents better simulates real low-resource settings. Sinhala and Nepali contain approximately 103 million and 110 million tokens, as used in Guzmán et al. (2019). We additionally extract the first 100 million French and Russian tokens for CC experiments.

6.4 Preprocessing

Training data is preprocessed separately for each unsupervised experiment as part of Artetxe et al. (2018b)'s training pipeline. Data is deduplicated, and tokenized and truecased using scripts from Moses (Koehn et al., 2007). Sentences with less than 3 tokens or more than 80 tokens are discarded, and sentences are shuffled. Ten thousand sentences are removed to form a development set. To begin the NMT phase, a joint BPE (Sennrich et al., 2016b) vocabulary of 32000 tokens is learned. Source- and target-side corpora are backtranslated using the final model from the SMT phase, and all data then has BPE applied.[8]

For supervised experiments, training data is tokenized and truecased, and then a joint BPE (Sennrich et al., 2016b) vocabulary of 32000 tokens is learned. After applying BPE, the data is cleaned using Moses' `clean-corpus-n.perl`, discarding sentences under 3 and greater than 80 tokens.

6.5 Vocabulary Overlap of Training Sets

A vocabulary of unigrams was collected for each target-side (English) corpus, which includes tokens that appear at least 10 times, for a maximum of 200,000 unigrams. Of approximately 144,000 such unique tokens between UN-A and UN-B from the Fr-En UN corpus, the corpora share 54.1%. These corpora are used in the Disjoint condition. The respective vocabulary overlap for UN-A and CC from the Diff. Dom condition for Fr-En is 25.7%. For UN-B vs. CC for Fr-En, they share 25.3%. Statistics are analogous for Ru-En.

6.6 Test and Validation Sets

Ru-En models are tested on newstest2019. Fr-En models are tested on newstest2014. Supervised models use newstest2018 (Ru-En) or newstest2013 (Fr-En) for validation. For Si-En and Ne-En, we use the Wikipedia dev and devtest sets from Guzmán et al. (2019).[9] For supervised models, we select the ensemble with best performance on newstest2017 (Ru-En) or newstest2012 (Fr-En).

7 Reinvestigation of Artetxe et. al.

First, we replicate Artetxe et al. (2018b, 2019), achieving relatively comparable results (Table 2). Differences in BLEU scores are likely attributable to using Artetxe et al. (2018b)'s code for all steps before the NMT phase; Artetxe et al. (2019) improved upon these, but we chose to use the publicly available code from the previous year.

	Artetxe et al. (2019)	**This Work**
Fr-En	33.2	31.1
En-Fr	33.6	32.8

Table 2: Artetxe et al. (2019)'s unsupervised MT performance vs. the system in this work, which is a combination of Artetxe et al. (2018b) [steps before NMT] and Artetxe et al. (2019) [NMT component], using the full News crawl datasets from Subsection 6.2. Scored using SacreBLEU (Post, 2018) on newstest2014.

Next, we set up a series of experiments to assess the questions posed in Section 4. Results are presented in Tables 3 and 4.

7.1 Unsupervised Quality Loss

The Supervised ("Sup.") column of Table 3 shows performance of a standard Transformer-big architecture on parallel bitext for Ru-En and Fr-En. Assuming that supervised translation will always outperform unsupervised, these scores represent a ceiling to quantify how much potential quality is lost using an unsupervised architecture.

[8] Some experiments had Moses' `clean-corpus-n.perl` applied after this.

[9] https://github.com/facebookresearch/flores/raw/master/data/wikipedia_en_ne_si_test_sets.tgz

	Sup.	Parallel	Disjoint	Diff. Dom.
Corpus	A / A	A / A	A / B	A / CC*
Ru-En	26.9	23.7 *(-3.2)*	21.2 *(-5.7)*	0.7 *(-26.2)*
Fr-En	29.9	27.6 *(-2.3)*	27.0 *(-2.9)*	3.9 *(-26.0)*

Table 3: Unsupervised MT performance on a single run using the United Nations (UN) dataset. "Diff. Dom." uses UN data as source and Common Crawl (*) as target. "Sup." is supervised with UN parallel data. A / A refers to UN training dataset A used on the source and target sides, for example. Scored using SacreBLEU (Post, 2018) on newstest2019 (Ru-En) and newstest2014 (Fr-En).

.

The supervised models and those in the Parallel column use the same datasets[10] and can therefore be directly compared. We observe a BLEU score drop of ∼3.2 for Ru-En versus a drop of ∼2.3 for Fr-En when using the unsupervised architecture. This minor quality loss represents a strong result for unsupervised MT; however, the question is whether the results will remain strong as we gradually make the monolingual corpora less similar.

7.2 Investigating Our Research Questions

Does unsupervised machine translation work for:

(1) Dissimilar language pairs?

We conduct experiments in French and Russian into English. Whereas French and English share the same Roman script and common linguistic origin, Russian is a Slavic language that uses the Cyrillic script. The results presented in Tables 3 and 4 indicate that unsupervised MT is more difficult when writing script and language family differs. Across the board, we observe that the ΔBLEU between supervised and unsupervised performance is wider for Ru-En than for Fr-En, particularly for News and Common Crawl datasets. For instance, whereas Fr-En loses 2.9 BLEU in the Supervised versus Disjoint setups (which use comparable data), Ru-En loses 5.7 BLEU. While we acknowledge that in general one should not compare BLEU scores across language pairs or datasets, this gap suggests that unsupervised MT may behave differently for different language pairs.

(2) Dissimilar domains?

We investigate the effects of domain similarity between source and target training corpora. For each language, we observe the difference in performance on Table 3 of the Parallel, Disjoint, and Diff. Dom. columns.

Because training data in the Parallel condition was originally parallel, these experiments have the highest possible domain match between source and target data. Since Disjoint data was extracted from the same corpus but was not parallel, source and target can be thought of as having very slightly different domains. We observe a minor performance drop between Parallel and Disjoint experiments, which is more pronounced for Ru-En.

Examining the Diff. Dom. column, however, the performance contrast is stark. While both language pairs obtain respectable BLEU scores in the 20s when domains match in Parallel and Disjoint conditions, performance drops sharply when training set domains are mismatched—scoring 3.9 BLEU for Fr-En and 0.7 for Ru-En. (A subsequent run of Fr-En scored 17.4, addressed in Section 7.4). The fault is not with either side of the training corpus alone—Parallel/Disjoint experiments from Table 3 which use UN data alone and CC experiments in Table 4 which use Common Crawl data alone perform acceptably—it is when the two datasets are paired as source-target in Diff. Dom. conditions that performance rapidly deteriorates.

(3) Diverse datasets?

	UN	News	CC
Ru-En	21.2	16.1	13.8
Fr-En	27.0	28.2	22.4
Si-En	n/a	n/a	0.2
Ne-En	n/a	n/a	0.4

Table 4: Unsupervised MT performance on a single run using diverse datasets [UN = United Nations (Disjoint), News = News Crawl, CC = Common Crawl]. Scored using SacreBLEU (Post, 2018) on newstest2019 (Ru-En), newstest2014 (Fr-En), and the FLoRes Wikipedia evaluation sets (Si-En, Ne-En) (Guzmán et al., 2019).

Table 4 shows the results of experiments using three different training datasets. News crawl matches the domain of the test set exactly. UN data has a moderate domain match with the test set, and CC matches the least. Not unexpectedly, most experiments where training and test domain match perform better than when there is a domain mismatch. The exception is the News experiment for Ru-En, where the model performs considerably worse than the UN condition despite having a stronger domain match. Notably, News has approx-

[10] Differences in token count are due to the different preprocessing detailed in Section 6.4.

imately 2-3x less data than UN for each language pair. We suspect that for Fr-En, the relative ease of unsupervised translation for this language pair allowed the strong domain match with the test set to outweigh the lower amount of data. On the other hand, the relative difficulty of unsupervised MT in Ru-En made the system suffer too greatly in the lower-resource condition, to where it could not compensate with domain match.

(4) A true low-resource pair?

Facebook recently released test sets for Sinhala-English and Nepali-English, true low-resource language pairs which not only lack bitext, but monolingual data is of poor quality. These languages do not share a script or language family with English, and the data is out-of-domain with the English data. This reflects a real-world low-resource scenario where we would hope to benefit from unsupervised MT. We observe extremely poor results in Table 4, with Si-En achieving a BLEU score of 0.2, and 0.4 for Ne-En. Guzmán et al. (2019) achieve similarly poor results for these language pairs without using supplemental data from a related language.

7.3 BLEU During Training

Figure 2 shows translation performance for the experiments in Tables 3 and 4 at various steps during the unsupervised machine translation pipeline. Most SMT models improve performance slightly as a result of unsupervised MERT tuning, and more substantially after three rounds of iterative back-translation. Substantial improvement occurs as a result of NMT training for all models except the degenerate Diff. Dom conditions.

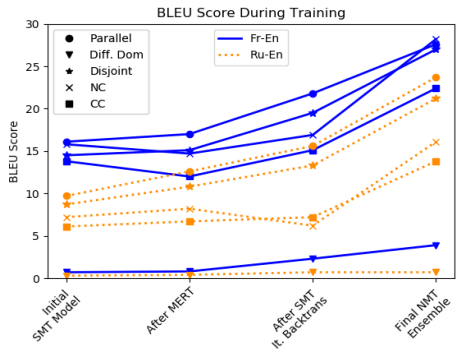

Figure 2: BLEU score during training.

7.4 Training Stability

One challenge with unsupervised methods is training stability: stochasticity during training can give substantially different results due to the iterative bootstrap nature of the training process.

	Condition	Min	Max	μ	σ
En-Fr	Repro	33.08	42.47	40.86	2.5
Fr-En	Repro	45.21	46.92	46.06	0.47
	Parallel	48.0	50.2	49.09	0.69
	Disjoint	37.88	39.09	38.47	0.37
	Diff. Dom.	**0.0**	**17.27**	**7.97**	**7.95**
	News	25.86	28.1	26.97	0.56
	CC	25.87	27.6	26.9	0.51
Ru-En	Parallel	32.24	34.04	32.95	0.47
	Disjoint	25.08	26.96	25.79	0.58
	Diff. Dom.	0.0	0.1	0.01	0.03
	News	22.19	23.77	23.1	0.44
	CC	**0.0**	**24.69**	**12.61**	**11.45**

Table 5: Accuracies (%) of induced dictionaries on 10-11 runs. Bold experiments were severely unstable.

In their analysis of unsupervised methods for generating CLEs, Glavaš et al. (2019) note considerable instability in performance on BLI. Defining failure as having a mean average precision (MAP) of $<$0.05 on all training runs, Iterative Closest Point (Hoshen and Wolf, 2018) fails for $\sim$21% of language pairs, Gromov-Wasserstein Alignment (Alvarez-Melis and Jaakkola, 2018) for $\sim$46%, and MUSE (Conneau et al., 2018) for $\sim$54%. VecMap (Artetxe et al., 2018a) succeeds for all language pairs, leading Glavaš et al. to deem it the most robust. Artetxe et al. (2018a) demonstrate their robustness over other methods in their work. When counting successful runs as achieving $>$5.0% accuracy, VecMap is successful 10/10 times for three language pairs. Hartmann et al. (2019) also investigate instability in vector space alignment methods.

After training phrase embeddings for each experiment, we run VecMap on the generated embedding spaces ten additional times and indeed find little fluctuation in BLI between runs. When rerunning the full pipeline for each experiment, however, we observe considerable instability in two experiments which dramatically affects downstream results.

We build a gold-standard bilingual dictionary of 2000 word pairs from Wikipedia data (Wołk and Marasek, 2014) available publicly on OPUS (Tiedemann, 2012), and run the first four steps of the unsupervised training procedure additional times for each experiment. Table 5 contains the summary results of 10-11 runs of each experiment.

Tables 3 and 4 present the results of the single

first run of each experiment. Whereas the majority have consistent accuracy on bilingual lexicon between runs as seen in Table 5, Diff. Dom. for Fr-En and CC for Ru-En are highly unstable. The BLI accuracy of additional runs of Fr-En Diff. Dom. ranged between 0.0% and 17.27%. Of the initial run and 9 subsequent, five had accuracies <0.1%, while the other five had accuracies >15.26%. For Ru-En CC, the run reported in Table 4 had a BLI accuracy of 21.35%. Of eleven runs, five had an accuracy <0.26%, and six had an accuracy >21.35%.

As evidence of the critical effect of BLI accuracy on downstream BLEU, whereas the Fr-En Diff. Dom. run reported in Table 3 had a BLI accuracy of 0.0%, a subsequent run of the entire training pipeline had an accuracy of 17.08% and a final BLEU score of 17.4. (This experiment is not included in the summary statistics of Table 5).

The unsupervised pipeline begins with preprocessing (deterministic, except shuffling and random selection of development set), language model training with KenLM (Heafield, 2011) (deterministic), followed by phrase embedding training using phrase2vec (non-deterministic), and then embedding space mapping with VecMap (non-deterministic). Because performance on reruns of VecMap alone was stable while holding the rest of the system constant, we must conclude that the dramatic instability is caused by either a poor embedding initialization from phrase2vec/word2vec, or VecMap's inability to handle certain monolingual vector space configurations. Apparently, the initial formation of monolingual vector spaces dramatically affects VecMap's ability to converge to a good solution, which in turn results in highly variable downstream translation performance.

To observe the relationship between BLI accuracy and downstream BLEU score, we direct the reader to Figure 3, where BLI accuracy after the VecMap phase of experiments from Tables 3 and 4 are displayed in relation to the final BLEU score.

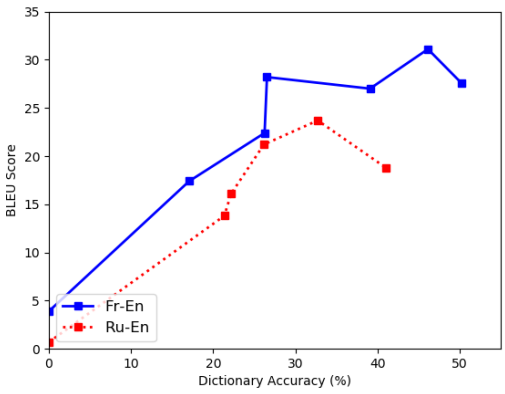

Figure 3: Relationship between bilingual lexicon induction accuracy after VecMap mapping, and final BLEU.

8 Discussion

Except in the Diff. Dom. condition, unsupervised MT performance for Fr-En is impressive and suggests that sentence alignment may not be required for successful MT under ideal conditions. Ru-En results are also impressive, but show that unsupervised MT still struggles when language pairs are dissimilar, especially when data amount is reduced.

The gap between Disjoint and Diff. Dom. conditions is perhaps the most striking result in our experiments. It suggests that one cannot naively collect monolingual corpora without considering their relative domain similarity; this may be a challenge in low-resource conditions, where there is less flexibility with data sources. Vulić et al. (2019) make a similar claim about unsupervised CLEs, stating "UNSUPERVISED methods are able to yield a good solution only when there is no domain mismatch and for the pair with two most similar languages (English-Spanish), again questioning their robustness and portability to truly low-resource and more challenging setups". Furthermore, the extremely poor results of Ne-En and Si-En reflect the reality of low-resource translation; the compound negative effects of language dissimilarity, domain mismatch between monolingual corpora, domain mismatch with the test set, and low amounts of low-quality data. It is the "worst of all worlds"—but reflects how current models might perform on the use cases for which they are needed. These challenges highlight the importance of evaluating unsupervised MT under varying realistic data conditions. Our evaluation is a step towards this goal, and identifies multiple areas for improvement.

A critical step in state-of-the-art unsupervised MT is methods for creating CLEs. Several authors have pointed out that "mapping" methods like VecMap assume that monolingual vector spaces are structurally similar, but that this "approximate isomorphism assumption" is increasingly tenuous as languages and domains diverge (Søgaard et al., 2018; Ormazabal et al., 2019; Glavaš et al., 2019; Vulić et al., 2019; Patra et al., 2019). Patra et al. (2019) find this for Fr-En and Ru-En specifically,

the languages examined in this work. Nakashole and Flauger (2018) argue that while linearity may hold within local "neighborhoods" of the vector space, the global mapping is non-linear. Søgaard et al. (2018) use their eigenvector similarity metric to show a strong correlation between vector space similarity and BLI performance. Analysis of the CLEs from our experiments demonstrate a relationship between BLI performance and downstream BLEU on the translation task. Coupled with our empirical evidence, the works cited in this section suggest that nonisometric vector spaces lead to poor quality translation.

Factors observed in our experiments that lead to lower quality translation can be attributable to a "weak isomorphism" between the monolingual vector spaces. Dissimilar languages means increasingly different distributional characteristics of words. Data from different domains naturally have different word frequencies and distributional characteristics, which become more pronounced as domains diverge. Because mapping methods rely on structural similarity of vector spaces, experiments using either UN or CC data alone had acceptable downstream performance, where as combining the datasets as source and target resulted in extremely poor translation. We observe the critical effect of word embedding initialization on BLI performance and downstream BLEU, suggesting that stochasticity during word embedding creation can cause resulting vector spaces to be more or less isomorphic. Finally, more data can give a more accurate distribution of words in comparison with the true distribution in the language, leading to a more realistic monolingual vector space. With less data, word embeddings are dependent on the smaller training sample, which may not match the test set or reflect true distributional properties of the language. Combining all of these negative factors likely leads to highly nonisomorphic monolingual embedding spaces, as demonstrated by the very poor Si-En and Ne-En results.

9 Conclusion & Future Work

Progress in unsupervised MT has been impressive, achieving performance near its supervised counterparts under some scenarios. That said, evaluating current approaches under broader settings and datasets reveals that unsupervised MT struggles in realistic low-resource scenarios. As stated by Lample et al. (2018b), "It's an open question whether there are more effective instantiations of these principles [underlying recent successes in fully unsupervised MT] or other principles altogether". In this work, we find that there is room for improvement to become robust to (1) dissimilar languages pairs, (2) dissimilar domains, (3) diverse datasets, and (4) the low-quality data of true low-resource languages—factors ubiquitous in low-resource language pairs for which unsupervised MT is intended. We find that (a) performance rapidly declines when source and target corpora are from different domains, and (b) stochasticity during word embedding training can dramatically affect downstream translation results. The latter is a yet unexplored research area. Future work should also evaluate pretraining methods in bilingual and multilingual training contexts.

Finally, we argue for extensive evaluation of unsupervised MT systems under varying data conditions to assess failure cases and encourage pursuit of promising paradigms. Doing so is a step towards solving the real-world problems of low-resource machine translation.

Language Models not just for Pre-training: Fast Online Neural Noisy Channel Modeling

Abstract

Pre-training models on vast quantities of unlabeled data has emerged as an effective approach to improving accuracy on many NLP tasks. On the other hand, traditional machine translation has a long history of leveraging unlabeled data through noisy channel modeling. The same idea has recently been shown to achieve strong improvements for neural machine translation. Unfortunately, naïve noisy channel modeling with modern sequence to sequence models is up to an order of magnitude slower than alternatives. We address this issue by introducing efficient approximations to make inference with the noisy channel approach as fast as strong ensembles while increasing accuracy. We also show that the noisy channel approach can outperform strong pre-training results by achieving a new state of the art on WMT Romanian-English translation.

1 Introduction

Unlabeled data has been leveraged in many ways in natural language processing including back-translation (Bojar and Tamchyna, 2011; Sennrich et al., 2016b; Edunov et al., 2018), self-training (He et al., 2020), or language model pre-training which led to improvements in many natural language tasks (Devlin et al., 2019). While pre-training has achieved impressive results on tasks where labeled data is limited, improvements in settings with abundant labeled data are modest (Raffel et al., 2020) with controlled studies showing a clear trend of diminishing returns as the amount of training data increases (Edunov et al., 2019).

In this paper, we focus on noisy channel modeling for text generation tasks, a classical technique from the statistical machine translation literature which had been the workhorse of text generation tasks for decades before the arrival of neural sequence to sequence models (Brown et al., 1993; Koehn et al., 2003). Unlike pre-training approaches, this approach is very effective irrespective of the amount of labeled data: since a recent revival (Yu et al., 2017; Yee et al., 2019), it has been an important part in the winning entries of several high resource language pairs at WMT 2019 (Ng et al., 2019), improving over strong ensembles that used 500M back-translated sentences. At the low resource WAT 2019 machine translation competition, noisy channel modeling was also a key factor for the winning entry (Chen et al., 2019).

Noisy channel modeling turns text generation on the head: instead of modeling an output sequence given an input, Bayes' rule is applied to model the input given the output, via a backward sequence to sequence model which is combined with the prior probability of the output, typically a language model. This enables the effective use of strong language models trained on large amounts of unlabeled data. The role of the backward model, or the channel model, is to validate outputs preferred by the language model with respect to the input.

A straightforward way to use language models is to pair them with standard sequence to sequence models (Gülçehre et al., 2015; Stahlberg et al., 2018). However, this does not address *explaining away effects* under which modern neural sequence models still suffer (Klein and Manning, 2001; Li et al., 2019). As a consequence, models are susceptible to producing fluent outputs that are unrelated to the input (Li et al., 2019). The noisy channel approach explicitly addresses this via the channel model.

However, a major obstacle to efficient noisy channel modeling is that generating outputs is much slower than decoding from a standard sequence to sequence model. We address this issue by introducing several simple yet highly ef-

† Work done while at Facebook during a Facebook AI Residency.

Proceedings of the 5th Conference on Machine Translation (WMT), pages 584–593
Online, November 19–20, 2020.

fective approximations which increase the speed of noisy channel modeling by an order of magnitude to make it practical. This includes smaller channel models as well as scoring only a subset of the channel model vocabulary. Experiments on WMT English-Romanian translation show that noisy channel modeling can outperform recent pre-training results. Moreover, we show that noisy channel modeling benefits much more from larger beam sizes than strong pre-training methods.

2 The Noisy Channel Approach

We assume a sequence to sequence task that takes the input x to predict the output y. A standard sequence to sequence model directly estimates the probability $p(y|x)$, referred to as a *direct model*. On the other hand, the noisy channel approach applies Bayes' rule to model $p(y|x) = p(x|y)p(y)/p(x)$ where $p(x|y)$ predicts the source x given the target y and is referred to as the *channel model*, $p(y)$ is a language model over the target y, and $p(x)$ is generally not modeled since it is constant for all y.

Yee et al. (2019) use Transformer models to parameterize the direct model, the channel model and the language model. Similar to Yu et al. (2017), they use the following linear combination of the channel model, the language model as well as the direct model for decoding:

$$\frac{1}{t}\log p(y|x) + \frac{\lambda_1}{s}\log p(x|y) + \frac{\lambda_2}{s}\log p(y) \quad (1)$$

where t is the length of the output prefix y, s is the length of the input sequence, and λ_1, λ_2 are hyperparameters.

Exact noisy channel model scoring with neural networks during decoding is prohibitively expensive since it requires a separate forward computation with the channel model for every token in the target vocabulary. To side step this issue, Yu et al. (2017) propose the following approximations to beam search with beam width k_1: determine the k_2 highest scoring extensions of each beam according to the direct model, then score the resulting $k_1 \times k_2$ partial candidates by the direct model, the channel model and the language model using the linear combination in Equation 1. Finally, this set is pruned to beam size k_1.

Despite this approximation, noisy channel decoding is still significantly slower than decoding with the direct model alone as shown in Figure 1.

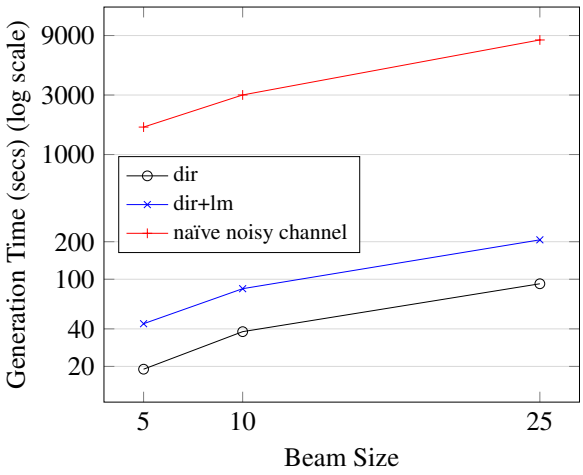

Figure 1: Speed of decoding with a direct model (`dir`), direct model with language model (`dir + lm`) and a naïve noisy channel approach without fast approximations or optimizations. The latter is very slow compared to the direct model. Results are based on generation with the fastest batch size for each setting with beam 5 on newstest2016 De-En (cf. §4.1).

The reason for this is that the channel model repeatedly scores the entire input sequence at each time-step and this is done k_2 times for each beam. Specifically, both the direct model and the language model compute $k_1 \times V$ scores at each time-step in order to make a decoding decision for each target token during beam search, where V denotes the vocabulary size which we assume to be similar between the input and output. In contrast, the channel model computes $k_1 \times k_2 \times S \times V$ scores for each target token, where S is the maximum source sequence length. This adds substantial compute and memory overhead, to the extent that the batch size at decoding often needs to be substantially reduced. This leads to slower inference on GPUs since less computation can be parallelized.

3 Fast Noisy Channel Modeling

Naïve online noisy channel modeling is significantly slower than standard direct models. In this section, we present approximations to make noisy channel modeling substantially faster.

3.1 Reducing Channel Model Size

Prior work on neural noisy channel used channel models which were of the same size as the direct model (Yu et al., 2017; Yee et al., 2019). The most recent work uses standard Transformer models (Yee et al., 2019; Ng et al., 2019; Yu et al., 2020). In this study, we hypothesize that the primary role

of the channel model is to avoid *explaining away effects* by the language model. This primarily entails assigning low scores to unrelated outputs, which may not require a very powerful model. In this case, we may be able to substantially decrease the size of the channel model at only a small loss in accuracy.

Recent work demonstrates that direct models with shallow decoders can give comparable accuracy, while being faster at inference time, compared to models with deep decoders (Wu et al., 2019; Elbayad et al., 2020; Kasai et al., 2020; Fan et al., 2020). This is particularly attractive for direct models for which the decoder network accounts for most of the wall time during inference but the dynamics for channel models are different: the channel model repeatedly scores the entire input sequence given progressively larger target prefixes. Unlike for direct models, there is no straightforward way to reuse the encoder output between time-steps, and we opt to recompute the entire encoder and decoder of the channel model at every target time-step. Since the input sequence is given, channel model computation can be batched over all tokens in the target prefix and the input sequence. This implies that we are free to adjust both the encoder and decoder depth.

We pursue two strategies to reduce model size: first, we progressively reduce the model dimension of the `base` Transformer architecture, by first halving the model dimension from 512 to 256, as well as the feed forward dimension from 2048 to 1024 for the `half` model. The smallest configuration uses a model dimension of just 32 and a feed forward dimension of 128 (denoted as `16th` model). Second, we consider models with only a single encoder block and a single decoder block. These models have a postfix `_1_1`, e.g., `16th_1_1`. Table 1 shows the various model sizes as well as accuracy on the development set, newstest2016.

	Parameters (M)	BLEU
big	282.7	38.0
big_1_1	93.8	34.1
base	72.1	36.7
base_1_1	23.6	31.2
half	25.1	33.6
half_1_1	15.8	27.4
quarter	9.8	28.4
quarter_1_1	7.5	22.0
16th	2.8	15.9
16th_1_1	2.7	10.0

Table 1: Smaller channel models in terms of number of total parameters as well as BLEU (avg. over 3 seeds) on the development set. All models have six blocks each in the encoder and the decoder, except for models ending in "_1_1" which have only a single block in the encoder and the decoder.

3.2 Reducing the Output Vocabulary

During online noisy channel decoding, we need to allocate memory for a large number of channel model output probabilites ($k_1 \times k_2 \times S \times V$, as explained in § 2). This substantially reduces the maximum possible batch size in order to prevent running out of memory while decoding on GPUs. A small batch size prevents the full utilization of parallel computation on GPUs, particularly, when the channel model is relatively small: some of our channel models have an embedding dimension of just 32.

To address this issue, we make use of the fact that we know exactly which input tokens need to be scored (since the input sequence is given) instead of computing probabilities for the entire vocabulary. This is similar to vocabulary reduction techniques used for early neural sequence to sequence models, and it is particularly convenient since we know exactly which tokens are in the input sequence (Mi et al., 2016; L'Hostis et al., 2016).

Similar to prior work on vocabulary reduction, we found it useful to not just score the input words but also a subset of the most frequent words in the vocabulary. Specifically, for each batch, we enumerate all input word types, add the 500 most frequent types and then compute output probabilities for this subset with the channel model. The number of output probabilities calculated is typically at least one order of magnitude smaller than the full vocabulary, as shown in § 5.4.1.

This approach substantially reduces the memory footprint of small channel models and enables the use of much larger batch sizes which leads to faster inference as we will see in § 5.

3.3 Reducing the Number of Candidates

We also study the effect of reducing the number of next token candidates k_2 scored for each beam at each step of beam search. This reduces the computation as well as memory overhead of channel model scoring.

4 Experimental Setup

4.1 Datasets

We consider two datasets for our experiments: For German-English (De-En), we train on WMT'19 training data. Following (Ng et al., 2019), we apply language identification filtering (Lui and Baldwin, 2012) and remove sentences longer than 250 tokens as well as sentence pairs with a source/target length ratio exceeding 1.5. This results in 26.8M sentence pairs. We validate on newstest2016 and test on newstest2014, newstest2015, newstest2017, and newstest2018. For all models, the source vocabulary is a 24K byte pair encoding (BPE; Sennrich et al., 2016) learned on the source portion of the bitext. For the target side, we use the vocabulary of the language model (§4.2) so that both models score the exact same units during beam search.

For Romanian-English (Ro-En), we train on WMT'16 training data, comprising 612K sentence pairs, validate on newsdev2016 and test on newstest2016. We learn a joint BPE vocabulary of 18K types on the bitext training data which is used for both the source and target. Different to German-English, we learn a joint BPE vocabulary to enable sharing the source and target embeddings which we found to perform better for Romanian-English in early experiments.

4.2 Language Models

For German-English, we train a sentence-level English Transformer language model with 16 layers and Transformer-Big architecture (Vaswani et al., 2017; Radford et al., 2018). The model is trained on de-duplicated English Newscrawl data from 2007-2018 comprising 186 million sentences or 4.5B words after normalization and tokenization. We use a BPE vocabulary of 24K types learned on this data. For Romanian-English translation, we train a similar English Transformer language model that uses the joint BPE vocabulary learned on the Romanian-English bitext. The latter enables the LM to score the exact same units as the sequence to sequence model during beam search.

We train a sentence-level Romanian Transformer language model with 16 layers and Transformer-Big architecture. The model is trained on de-duplicated Romanian CommonCrawl data consisting of 623M sentences or 21.7B words after normalization and tokenization (Conneau et al., 2019; Wenzek et al., 2020).

The German-English bitext training data as well as the language model training data are preprocessed with the Moses tokenizer (Koehn et al., 2007). We normalize punctuation and remove non-printing characters. Romanian-English data is preprocessed following Sennrich et al. (2016a) by applying Moses tokenization and special normalization for Romanian text.[1]

4.3 Translation Models

For De-En, we use the Transformer-Big architecture for the direct model. We do not share encoder and decoder embeddings since the source and target vocabularies are different. For channel models, operating from English to German, we consider different variants (§3.1, Table 1) to better understand the speed-accuracy trade-off of decreasing the capacity of channel models.

For Ro-En and En-Ro with bitext only, the direct and channel models use a Transformer-Base architecture. For Ro-En with backtranslation, the direct and channel models use a Transformer-Big architecture. We share the encoder and decoder embeddings since the source and target vocabularies are the same and because this improved accuracy.

4.4 Online Noisy Channel Decoding Setup

In order to set weights for the linear combination of model scores (Equation 1), we randomly sample a set of hyperparameters and evaluate each configuration on the development set (Yee et al., 2019; Ng et al., 2019). Hyperparameters are sampled within the interval $[0, 2]$, For direct models (`dir`), we sample ten random weights for the length penalty. For direct models combined with language models (`dir + lm`), we evaluate 100 randomly sampled configurations for the length penalty and the language model weight (λ_2). For direct models combined with language models and channel models (`dir + lm + ch`), we evaluate 1000 configurations of the length penalty, the language model weight (λ_2) and the channel model weight (λ_1). We use 16-bit floating point precision (Ott et al., 2018, 2019) for decoding with the online noisy channel setup.

Accuracy is measured via sacreBLEU (Post, 2018) for WMT German-English. We report the average BLEU of the newstest2014-2015 and newstest2017-2018 test sets, averaged over 3 random seeds for model weight initialization. Speed

dir + lm + quarter_1_1	8	40.2	63
dir + lm + 8th_1_1	5	40.3	60
dir + lm + 16th_1_1	3	40.2	56

Table 3: Smaller channel models perform similarly for the standard beam size of 5. We exploit this fact to speed up noisy channel decoding.

is measured by the generation time (averaged over 3 trials) in seconds on the German-English newstest2016 test set on a 32GB Volta V100 GPU using 16-bit floating point precision (Ott et al., 2018, 2019). Unless otherwise specified, the beam size is 5, and the number of candidates for noisy channel model scoring per beam is $k_2 = 10$, unless otherwise specified. Generation times are based on a tuned batch size for each model configuration. We select the batch size within $(1, 10, 25, 50, 75, 100, 125, 150, 200, 300)$ that fits in memory and results in the fastest generation time.

5 Results

5.1 Fast Noisy Channel Modeling

In the first experiment, we evaluate the speed and accuracy of fast noisy channel decoding (§ 3) and compare to the naïve version without approximations (Yee et al., 2019). As additional baselines, we consider a single direct model (`dir`), ensembling two direct models (`2 dir`) and three direct models (`3 dir`), as well as adding a language model to each (`lm`). As channel models, we consider a `big` Transformer, a `base` Transformer, as well as a variant with model dimension of only 32 which is 1/16th of the model dimension of a `base` Transformer with a single layer in the encoder and decoder each (`16th_1_1`), totaling just 2.7M parameters. For fast noisy channel decoding, we reduce the channel model output vocabulary (§3.2) and set $k_2 = 3$; we ablate these choices in § 5.4.

Table 2 shows that the approximations we introduce to make noisy channel decoding fast also achieve similar accuracy (40.5 BLEU) to the much slower noisy channel approach of (Yee et al., 2019), while being about six times faster at inference time.

Table 2 also shows that `dir + lm + 16th_1_1` is 0.7 BLEU score better than `3 dir` at a similar decoding speed. Thus, using a small channel model and a language model with online noisy channel decoding is a better strategy than ensembling 3 direct models. Noisy channel decoding is also complementary to ensembling direct models: `3 dir + lm + base_1_1` improves by 0.7 BLEU compared to `3 dir + lm`.

Table 3 compares fast noisy channel decoding with different channel model sizes. Generally, smaller channel models are only slightly less accurate than larger models while being significantly faster than their larger counterparts. For example,

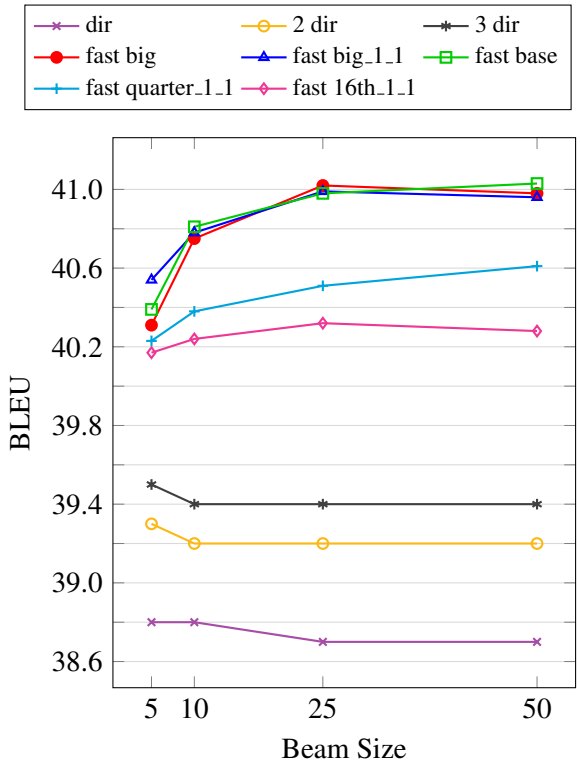

Figure 2: BLEU of fast online noisy channel decoding with different channel models when beam size is increased (compared to ensemble baselines). BLEU is averaged over news2014, news2015, news2017 and news2018 of WMT De-En.

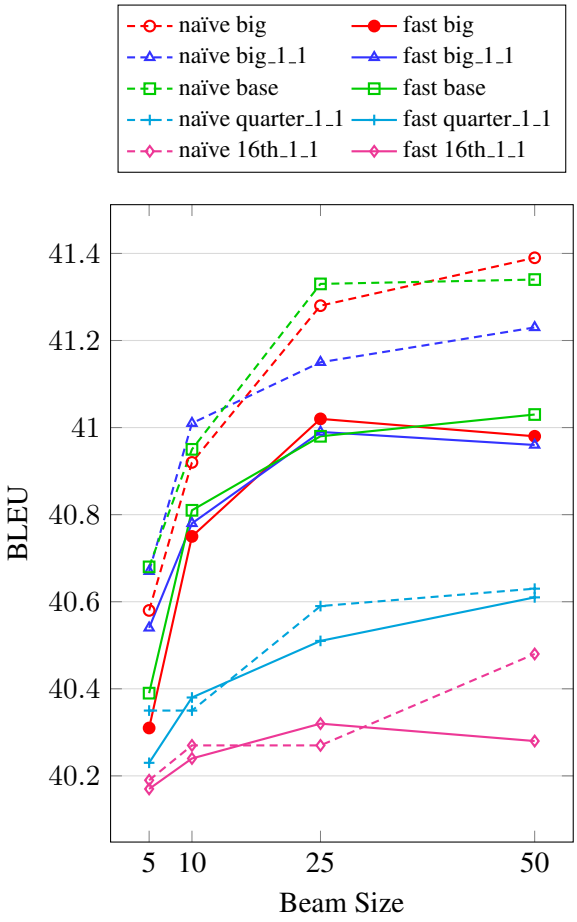

Figure 3: BLEU of fast and naïve online noisy channel decoding with different channel models sizes when beam size is increased. BLEU is averaged over news2014, news2015, news2017 and news2018 of WMT De-En.

`16th_1_1` is over eight times faster than `big` and achieves nearly the same accuracy.

This observation is in line with the hypothesis that the primary role of the channel model is to tie back the language model generations to the input. We exploit the fact that small channel models work well to make noisy channel decoding very fast.

5.2 Noisy Channel Decoding with Larger Beam Sizes

So far we used a standard beam size of five to enable fast decoding. However, previous work found that noisy channel modeling benefits more from larger beam sizes than other methods (Yee et al., 2019). Next, we evaluate whether our efficiency improvements still enable good performance with larger beam sizes.

Figure 2 shows that for beam size 5, most channel models perform comparably. Larger models are slightly better but overall they are in a similar ball park. As the beam size increases, larger channel models do achieve better accuracy. However, there is no difference between a single layer big model (`big_1_1`) and a six layer version (`big`). As observed in previous work (Yee et al., 2019), the direct model and the direct ensembles (`dir`, `2 dir`, `3 dir`) do not benefit from larger beam sizes.

Next, we compare fast noisy channel decoding and naïve noisy channel decoding at larger beam sizes. As shown in Figure 4, the naïve approach is much slower. Fast approximations to noisy channel decoding scale much better in terms of speed as the beam size increases. Figure 3 compares the accuracy of fast noisy channel decoding at larger beam sizes with that of naïve noisy channel decoding. Using the `big` and `big_1_1` channel models gives the best performance across all beam sizes for naïve noisy channel decoding. With fast noisy channel decoding, we see an average drop of 0.3 BLEU and 0.2 BLEU for `big` and `big_1_1` respectively. On the other hand, for smaller channel models, the difference between naïve and fast noisy

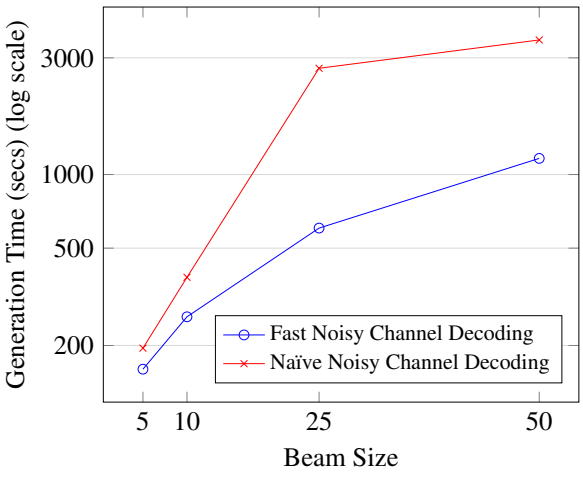

Figure 4: With larger beam sizes, the speed of fast approximations for noisy channel decoding scales much better than that of naïve noisy channel decoding. Results are based on generation using the `big_1_1` channel model with the fastest batch size for each setting with beam 5 on newstest2016 De-En.

channel decoding is generally smaller.

5.3 Results on WMT Romanian-English

Next, we evaluate noisy channel modeling on WMT Romanian-English translation (Ro-En and En-Ro) which is a low resource setup compared to WMT German-English. We also compare to a recently introduced pre-training approach, mBART. The mBART model is pre-trained to denoise input sentences in multiple languages, followed by fine-tuning on the bitext (Liu et al., 2020). Following their setup for En-Ro evaluation, we apply Moses tokenization and normalize diacritics for Romanian (Sennrich et al., 2016a), and use tokenized BLEU. For Ro-En, we use SacreBLEU (Post, 2018).

Table 4 shows that noisy channel decoding with a wide beam can outperform multilingual pre-training (mBART) across the board. Large beams are not helpful for generation with mBART. Compared to the direct model, noisy channel decoding improves by 2.7/3.1 BLEU on En-Ro and Ro-En respectively, and increasing the beam size gives gains of 4.5/4.5 BLEU.

We also study the performance of noisy channel decoding on Romanian-English with back-translated data generated using unrestricted sampling (Edunov et al., 2018).[2] As compared to mBART02 (Liu et al., 2020), the previous state-of-the-art result on Romanian-English with back-translation, we achieve a 0.5 BLEU improvement. We use a similar number of total model parameters, but much less monolingual English data. Our English language model is trained on 4.5B tokens, while mBART02 uses 66B tokens of English and Romanian monolingual data.

Finally, Table 5 shows that fast approximations and smaller channel models achieve similar performance but much higher speed compared to naïve noisy channel decoding on WMT Romanian-English with back-translation. Fast noisy channel decoding with `base_1_1` achieves comparable accuracy as mBART02 at slightly faster generation time with beam size 5.

5.4 Ablations

In this section we focus on some of the design choices we made to speed up noisy channel decoding. We measure the impact on speed and accuracy when reducing the output vocabulary size of the channel model, and reducing the number of beam candidates scored by the channel model.

5.4.1 Reducing the Output Vocabulary

In the next experiment, we compare the speed of using the full output vocabulary for the channel model to a reduced version. Specifically, we reduce the vocabulary by selecting all source tokens in the batch as well as the most frequent 500 tokens in the training data (see § 3.2). We tune each setup by selecting the fastest batch size based on a sweep over different batch sizes $(1, 10, 25, 50, 75, 100, 125, 150, 200, 300)$.

Table 6 shows that generating channel model scores for a small subset of the source vocabulary results in a small accuracy of up to 0.3 BLEU, but often less, while substantially increasing speed by 40-65% for single layer channel models and by 20-55% for other channel models. `base_1_1` with a small vocabulary is nearly ten times faster than the approach proposed in Yee et al. (2019) (channel model size `big`), with a slight decline in accuracy.

The average vocabulary size used for scoring the channel model is around 1050, as compared to full source vocabulary size of 28,048. This leads to a large reduction in memory consumption and enables fitting larger batches into memory.

[2]The monolingual English data used for backtranslation comes from `http://data.statmt.org/rsennrich/wmt16_backtranslations/` (Sennrich et al., 2016c).

	mono tokens Ro-En (B)	mono tokens En-Ro (B)	En-Ro	Ro-En	Ro-En +BT
mBART02	66	66	38.5	38.5	39.9

16th_1_1	40.2	209	40.2	74

Table 6: Comparison of accuracy (BLEU) and speed of online noisy channel decoding with and without the small output vocabulary approximation for different channel model sizes. Note we use $k_2 = 10$ for this ablation. BLEU is averaged over news2014, news2015, news2017 and news2018 of WMT De-En and generation time is on news2016.

5.4.2 Reducing the Number of Candidates

For each beam in each step of beam search, we need to make a choice about how many candidates k_2 we re-score with noisy channel modeling. Yee et al. (2019) re-scored $k_2 = 10$ candidates for each beam at each step. We sweep over different values of k_2 to understand the speed-accuracy trade-off associated with the choice of k_2. Table 7 shows that smaller values for k_2 are as accurate and much faster for beam size 5.

6 Conclusion

We introduced a number of approximations which greatly speed up noisy channel modeling for neural sequence to sequence models. This includes using channel models which are a fraction of the size of commonly used sequence to sequence models, pruning most of the channel model output vocabulary, and reducing the number of beam candidates scored by the channel model.

Our approximations are simple, yet, highly effective and enable comparable inference speed to ensembles of direct models while delivering higher accuracy. Our experiments show that noisy channel modeling can outperform pre-training approaches by being able to better exploit wider beams. Moreover, this is achieved while using a smaller amount of monolingual data.

k_2	BLEU	Time (s)
2	40.4	76
3	40.5	88
5	40.4	124
10	40.5	168

Table 7: Smaller number of rescoring candidates k_2 per beam are as accurate and much faster than larger values of k_2 for fast noisy channel decoding using `base_1_1` with beam 5. BLEU is averaged over news2014, news2015, news2017 and news2018 of WMT De-En and generation time is on news2016.

Abstract

Simultaneous translation involves translating a sentence before the speaker's utterance is completed in order to realize real-time understanding in multiple languages. This task is significantly more challenging than the general full sentence translation because of the shortage of input information during decoding. To alleviate this shortage, we propose multimodal simultaneous neural machine translation (MSNMT), which leverages visual information as an additional modality. Our experiments with the Multi30k dataset showed that MSNMT significantly outperforms its text-only counterpart in more timely translation situations with low latency. Furthermore, we verified the importance of visual information during decoding by performing an adversarial evaluation of MSNMT, where we studied how models behaved with incongruent input modality and analyzed the effect of different word order between source and target languages.

1 Introduction

Simultaneous translation is a natural language processing (NLP) task in which translation begins before receiving the whole source sentence. It is widely used in international summits and conferences where real-time comprehension is one of the essential aspects. Simultaneous translation is already a difficult task for human interpreters because the message must be understood and translated while the input sentence is still incomplete, especially for language pairs with different word orders (e.g. SVO-SOV) (Seeber, 2015). Consequently, simultaneous translation is more challenging for machines. Previous works attempt to solve this task by predicting the sentence-final verb (Grissom II et al., 2014), or predicting unseen syntactic constituents (Oda et al., 2015). Given the difficulty of predicting future inputs based on existing limited inputs, Ma et al. (2019) proposed a simple simultaneous neural machine translation (SNMT) approach `wait-k` which generates the target sentence concurrently with the source sentence, but always `k` tokens behind, satisfying low latency requirements.

However, previous approaches solve the given task by solely using the text modality, which may be insufficient to produce a reliable translation. Simultaneous interpreters often consider various additional information sources such as visual clues or acoustic data while translating (Seeber, 2015). Therefore, we hypothesize that using supplementary information, such as visual clues, can also be beneficial for simultaneous machine translation.

To this end, we propose Multimodal Simultaneous Neural Machine Translation (**MSNMT**) that supplements the incomplete textual modality with visual information, in the form of an image. It will predict still missing information to improve translation quality during the decoding process. Our approach can be applied in various situations where visual information is related to the content of speech such as presentations with slides (e.g. TED Talks[1]) and news video broadcasts[2]. Our experiments show that the proposed MSNMT method achieves higher translation accuracy than the SNMT model that does not use images by leveraging image information. To the best of our knowledge, we are the first to propose the incorporation of visual information to solve the problem of incomplete text information in SNMT.

The main contributions of our research are as follows. We propose to combine multimodal and simultaneous NMT, therefore, discovering cases where such multimodal signals are beneficial for

the end-task. Our MSNMT approach brings significant improvement in simultaneous translation quality by enriching incomplete text input information using visual clues. As a result of a thorough analysis, we conclude that the proposed method is able to predict tokens that have not appeared yet for source-target language pairs with different word order (e.g. English→Japanese). By providing an adversarial evaluation, we showed that the models indeed utilize visual information.

2 Related Work

For simultaneous translation, it is crucial to predict the words that have not appeared yet. For example, it is important to distinguish nouns in SVO-SOV translation and verbs in SOV-SVO translation (Ma et al., 2019). SNMT can be realized with two types of policy: fixed and adaptive policies (Zheng et al., 2019b). Adaptive policy decides whether to wait for another source word or emit a target word in one model. Previous models with adaptive policies include explicit prediction of the sentence-final verb (Grissom II et al., 2014; Matsubara et al., 2000) and unseen syntactic constituents (Oda et al., 2015). Most dynamic models with adaptive policies (Gu et al., 2017; Dalvi et al., 2018; Arivazhagan et al., 2019; Zheng et al., 2019a,c, 2020) have the advantage of exploiting input text information as effectively as possible due to the lack of such information in the first place. Meanwhile, Ma et al. (2019) proposed a simple `wait-k` method with fixed policy, which generates the target sentence only from the source sentence that is delayed by `k` tokens. However, their model for simultaneous translation relies only on the source sentence. In this research, we concentrate on the `wait-k` approach with fixed policy, so that the amount of input textual context can be controlled to analyze better whether multimodality is effective in SNMT.

Multimodal NMT (MNMT) for full-sentence machine translation has been developed to enrich text modality by using visual information (Hitschler et al., 2016; Specia et al., 2016; Elliott and Kádár, 2017). While the improvement brought by visual features is moderate, their usefulness is proven by Caglayan et al. (2019). They showed that MNMT models are able to capture visual clues under limited textual context, where source sentences are synthetically degraded by color deprivation, entity masking, and progressive masking. However, they use an artificial setting where they deliberately deprive the models of source-side textual context by masking. However, our research has discovered an actual end-task and has shown the effectiveness of using multimodal data for it. Compared with the entity masking experiments (Caglayan et al., 2019), where they use a model exposed to only `k` words, our model starts by waiting for the first `k` source words and then generates each target word after receiving every new source token, eventually seeing all input text.

In MNMT, visual features are incorporated into standard machine translation in many ways. Doubly-attentive models are used to capture the textual and visual context vectors independently and then combine these context vectors in a concatenation manner (Calixto et al., 2017) or hierarchical manner (Libovický and Helcl, 2017). Some studies use visual features in a multitask learning scenario (Elliott and Kádár, 2017; Zhou et al., 2018). Also, recent work on MNMT has partly addressed lexical ambiguity by using visual information (Elliott et al., 2017; Lala and Specia, 2018; Gella et al., 2019) showing that using textual context with visual features outperform unimodal models.

In our study, visual features are extracted using image processing techniques and then integrated into an SNMT model as additional information, which is supposed to be useful to predict missing words in a simultaneous translation scenario. To the best of our knowledge, this is the first work that incorporates external knowledge into an SNMT model.

3 Multimodal Simultaneous Neural Machine Translation Architecture

Our main goal is to investigate if image information would bring improvement on SNMT. As a result, two tasks could benefit from each other by combining them.

In this section, we describe our MSNMT model, which is composed by combining an SNMT framework `wait-k` (Ma et al., 2019) and a multimodal model (Libovický and Helcl, 2017). We base our model on the RNN architecture, which is widely used in MNMT research (Libovický and Helcl, 2017; Caglayan et al., 2017a; Elliott and Kádár, 2017; Zhou et al., 2018; Hirasawa et al., 2019). The model takes a sentence and its corresponding image as inputs. The decoder of the MSNMT model outputs the target language sentence in a simultaneous and multimodal manner by attaching

attention not only to the source sentence but also to the image related to the source sentence.[3]

3.1 Simultaneous Translation

We first briefly review standard NMT to set up the notations. The encoder of standard NMT model always takes the whole input sequence $\mathbf{X} = (x_1, ..., x_n)$ of length n where each x_i is a word embedding and produces source hidden states $\mathbf{H} = (h_1, ..., h_n)$. The decoder predicts the next output token y_t using $\mathbf{H}$ and previously generated tokens, denoted $\mathbf{Y}_{<t} = (y_1, ..., y_{t-1})$. The final output is calculated using the following equation:

$$p(\mathbf{Y}|\mathbf{X}) = \prod_{t=1}^{|\mathbf{Y}|} p(y_t|\mathbf{X}, y_{<t}) \quad (1)$$

Different from standard neural translation, in which each y_i is predicted using the entire source sentence $\mathbf{X}$, the simultaneous translation requires the model to translate concurrently with the growing source sentence. We incorporate the `wait-k` approach (Ma et al., 2019) for our simultaneous translation model. Instead of waiting for the whole sentence before translating, this model waits for only the first `k` tokens and starts to generate each target tokens after taking every new source token one by one. It stops taking new input tokens once the whole input sentence is on board. For example, if $\mathtt{k} = 3$, the first target token is predicted using the first 3 source tokens, and the second target token using the first 4 source tokens. The `wait-k` decoding probability $p_{\texttt{wait-k}}$ is:

$$p_{\texttt{wait-k}}(\mathbf{Y}|\mathbf{X}) = \prod_{t=1}^{|\mathbf{Y}|} p(y_t|\mathbf{X}_{\leq g(t)}, y_{<t}) \quad (2)$$

where $g(t)$ is the `wait-k` policy function which decides how much input text to read and translate, $\mathbf{X}_{\leq g(t)} = (x_1, ..., x_{g(t)})$ and $g(t)$ is $0 \leq t \leq n$. $g(t)$ is defined as follows:

$$g(t) = \min\{k + t - 1, n\} \quad (3)$$

When $k + t - 1$ is over source length n, $g(t)$ is fixed to n, which means the remaining target tokens (including current step) are generated using the full source sentence. For full sentence translation, $g(t)$ is constant $g(t) = n$.

[3]Our code is publicly available at: https://github.com/toshohirasawa/mst. We fixed our code based on the comments of Ozan Caglayan.

3.2 Multimodal Translation

We use a hierarchical attention combination technique (Libovický and Helcl, 2017) to incorporate visual and textual features into an MNMT model. This model calculates the independent context vectors from the textual features $\boldsymbol{h}^{\text{txt}} = (h_1^{\text{txt}}, ..., h_n^{\text{txt}})$ and the visual features $\boldsymbol{h}^{\text{img}} = (h_1^{\text{img}}, ..., h_m^{\text{img}})$, which are extracted by the textual encoder and the image processing model, respectively. It then combines the resulting two vectors using a second attention mechanism, which helps to perform simultaneous translation taking into account visual information.

Specifically, we compute the context vectors c_i^{f} for each image ($\text{f} = \text{img}$) and text ($\text{f} = \text{txt}$) modality independently using the following equations:

$$e_{i,j}^{\text{f}} = \Omega^{\text{f}}(s_i, h_j^{\text{f}}) \quad (4)$$

$$\alpha_{i,j}^{\text{f}} = \frac{\exp(e_{i,j}^{\text{f}})}{\sum_{l=1}^{|\mathbf{h}^{\text{f}}|} \exp(e_{i,l}^{\text{f}})} \quad (5)$$

$$c_i^{\text{f}} = \sum_{j=1}^{|\mathbf{h}^{\text{f}}|} \alpha_{i,j}^{\text{f}} h_j^{\text{f}} \quad (6)$$

where Ω^{f} is a feedforward network for each modality f; s_i is i-th decoder hidden state.

We project these image and text context vectors into a common space and compute another distribution over the projected context vectors and their corresponding weighted average using the second attention:

$$\tilde{e}_i^{\text{f}} = \Psi(s_i, c_i^{\text{f}}) \quad (7)$$

$$\beta_i^{\text{f}} = \frac{\exp(\tilde{e}_i^{\text{f}})}{\sum_{\text{r}\in\{\text{img,txt}\}} \exp(\tilde{e}_i^{\text{r}})} \quad (8)$$

$$\tilde{c}_i = \sum_{\text{r}\in\{\text{img,txt}\}} \beta_i^{\text{r}} W^{\text{r}} c_i^{\text{r}} \quad (9)$$

where Ψ is a feedforward network. Equation 8 calculates the second attention to combine the image and text vectors. W^{r} is a weight matrix used to compute the context vector $\tilde{c}_i$ calculated from image and text features. The final hypothesis $\mathbf{Y}$ has the probability:

$$p_{\text{mnmt}}(\mathbf{Y}|\mathbf{X}, \mathbf{Z}) = \prod_{t=1}^{|\mathbf{Y}|} p(y_t|\mathbf{X}, \mathbf{Z}, y_{<t}) \quad (10)$$

where $\mathbf{Z}$ represents input image features.

3.3 Multimodal Simultaneous Neural Machine Translation

In this subsection, we describe the structure of the MSNMT model, which is a combination of the models described in Sections 3.1 and 3.2. The method for calculating the image context vector is the same as for MNMT; however, the text context vector (Equation 6) for the t-th step is calculated as follows:

$$\hat{c}_i^{\text{txt}} = \sum_{j=1}^{g(t)} \alpha_{i,j}^{\text{txt}} h_j^{\text{txt}} \tag{11}$$

Thus $\hat{c}_i^{\text{txt}}$ is calculated from the input text prefix determined by `wait-k` policy function $g(t)$. Then we apply the second attention to $\hat{c}_i^{\text{txt}}$ and c_i^{img} in order to calculate $\tilde{c}_i$ (Equation 9).

The decoding probability becomes as follows:

$$p_{\text{msnmt}}(\mathbf{Y}|\mathbf{X},\mathbf{Z}) = \prod_{t=1}^{|\mathbf{Y}|} p(y_t|\mathbf{X}_{\leq g(t)},\mathbf{Z},y_{<t}) \tag{12}$$

4 Experimental Setup

4.1 Dataset

We experiment with our model in four translation directions consisting of 5 languages: English (En), German (De), French (Fr), Czech (Cs), and Japanese (Ja). All language pairs include En on the source side.

We used the train, development, and test sets from the Multi30k (Elliott et al., 2016) dataset published in the WMT16 Shared Task, which is a benchmark dataset generally used in MNMT research (Libovický and Helcl, 2017; Caglayan et al., 2019; Elliott and Kádár, 2017; Zhou et al., 2018; Hirasawa et al., 2019) for En→De, En→Fr and En→Cs.

Nakayama et al. (2020) released F30kEnt-JP dataset[4] which contains Japanese translations of first two original English captions for each image of the Flickr30k Entities dataset (Plummer et al., 2017). They follow the same annotation rules as the Flickr30k Entities dataset using exactly the same tags with entity types and IDs. We preprocessed this data as follows: 1) The parallel En→Ja data was created by taking alignment using corresponding IDs assigned to each Japanese translation entity with the IDs of Flickr30k entities.[5] 2) The created parallel data was aligned with its corresponding images using text files named $(image\_id).txt$ corresponding to each image in Flickr30k. 3) Finally, the created multimodal data was split to train, dev, and test following data splits of Multi30k using the same Multi30k image IDs. Note that the English side of En→Ja parallel data extracted from F30kEnt-JP and English side of Multi30k data are thought to be somewhat comparable but not strictly the same while their corresponding images are the same.

Data split for all language pairs were as follows: training set, 29,000 sentence pairs, development set, 1,014 sentence pairs, and 1,000 sentence pairs for the test set. This dataset's average sentence length is 12-13 tokens for En, De, Fr, Cs and 20 tokens for Ja.

We limit the vocabulary size of the source and the target languages after concatenating them to 10,000 sub-words (Sennrich et al., 2016). All sentences are preprocessed with lower-casing, tokenizing, and normalizing the punctuation using the Moses script[6]. To tokenize Japanese sentences, we used MeCab[7] with the IPA dictionary.

Visual features are extracted using pre-trained ResNet (He et al., 2016). Technically, we encode all images in Multi30k with ResNet-50 and pick out the hidden state in the pool5 layer as a 2,048-dimension visual feature.

4.2 Systems

We compare the following models: **1. SNMT:** We use only text modality for training data as a baseline for each `wait-k` model. **2. MSNMT:** We use image modality along with text modality for a training data for each `wait-k` model.

To train the above models, we utilize attention NMT (Bahdanau et al., 2015) with a 2-layer unidirectional GRU encoder and a 2-layer conditional GRU decoder. We use the open-source implementation of the `nmtpytorch` toolkit v3.0.0 (Caglayan et al., 2017b). We first pre-train the MSNMT model for each `k` until convergence using only text data and use zeros for visual features. Then we continue training MSNMT on multimodal data for

[4] https://github.com/nlab-mpg/Flickr30kEnt-JP

[5] We used the second translations due to some empty translations of the first captions.

[6] We applied preprocessing using task1-tokenize.sh from https://github.com/multi30k/dataset.

each `k`. We employ early-stopping: the training was stopped when the BLEU score did not increase on the development set for 10 epochs for MSNMT pre-training, 5 epochs for MSNMT fine-tuning, and 15 epochs for SNMT training.

In order to keep our experiments as pure as possible, we will not use additional data or other types of models. It will allow us to control the amount of input textual context, so we can easily analyze the relationship between the amount of textual and visual information.

4.3 Hyperparameters

We use the same hyperparameters for SNMT and MSNMT for a fair comparison as follows. All models have word embeddings of 200 and recurrent layers of dimensionality 400 units with 2way sharing of embeddings in the network. We used Adam (Kingma and Ba, 2015) with a learning rate of 0.0004. Decoders were initialized with zeros. We used a minibatch size of 64 for training and 32 for fine-tuning. Rates of dropout applied on source embeddings, source encoder states and pre-softmax activations were 0.4, 0.5, and 0.5, respectively. We set the max length of the input to 100. `wait-k` experiments were conducted for 1, 3, 5, 7, and Full settings. For MSNMT only hyperparameters, the sampler type was set to approximate, and channels were set to 2048. The fusion type was set to hierarchical mode.

4.4 Evaluation

We report BLEU scores calculated using Moses' multi-bleu.perl, which is a widely used evalu-

Results are the average of four runs. **Bold** indicates the best BLEU score for each wait-k for each translation direction. "†" indicates the statistical significance of the improvement over Incongruent settings.

ation metric in MT, on our test sets for each wait-k model.[8] Statistical significance ($p < 0.05$) on the difference of BLEU scores was tested by Moses' *bootstrap-hypothesis-difference-significance.pl*. "Full" means that the whole input sentence is used as an input for the model to start translating. All reported results are the average of four runs using four different random seeds.

Additionaly, we use open-sourced Average Lagging (AL) latency metric proposed by Ma et al. (2019) to evaluate the latency for SNMT and MSNMT systems.[9] It calculates the degree of out of sync time with the input, in terms of the number of source tokens as follows:

$$\mathrm{AL}_g(\mathbf{X}, \mathbf{Y}) = \frac{1}{\tau_g(|\mathbf{X}|)} \sum_{t=1}^{\tau_g(|\mathbf{X}|)} g(t) - \frac{t-1}{r} \quad (13)$$

where $r = |\mathbf{Y}|/|\mathbf{X}|$ is the target-to-source length ratio and τ_g is the decoding step when source sentence finishes:

$$\tau_g(|\mathbf{X}|) = \min\{t | g(t) = |\mathbf{X}|\} \quad (14)$$

5 Results

Table 1 illustrates the BLEU scores of MSNMT and SNMT models on the test set. MSNMT systems show significant improvements over SNMT systems for all language pairs when input textual information is limited. Note that the difference of BLEU scores between MSNMT and SNMT becomes larger as the k gets smaller, especially when the target language is distant from English in terms of word order (e.g. Cs and Ja). On the other hand, the availability of more tokens during the decoding process ($k \geq 5$) leads to the text information becoming sufficient in some cases.

[8]Due to space constraints, we show results only for test sets.

[9]https://github.com/SimulTrans-demo/STACL

Figure 1 shows translation quality against AL for four language directions. In all these figures, we observe that, as k increases, the gap between BLEU scores for MSNMT and SNMT decreases. We also observe that AL scores are better for MSNMT as k decreases. From these results, it can be seen that in terms of latency, the smaller k is, the more beneficial the visual clues become.

6 Analysis

In this section, we provide a thorough analysis to further investigate the effect of visual data to produce a simultaneous translation by (a) providing adversarial evaluation; and (b) analyzing the impact of different word order for En→Ja language pair.

6.1 Adversarial Evaluation

In order to determine whether MSNMT systems are aware of the visual context (Elliott, 2018), we perform the adversarial evaluation on the test set. We present our system with correct visual data with its source sentence (Congruent) as opposed to random visual data as an input (Incongruent) (Elliott, 2018).Therefore, we reversed the order of 1,000 images of the test set, so there will be no overlapping congruent visual data. Then we reconstruct image features for those images to use as an input.

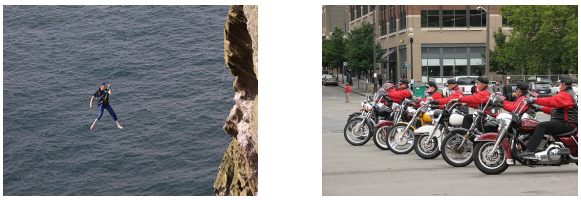
Results of image awareness experiments are shown in Table 2. We can see the large difference in BLEU scores between MSNMT congruent (C columns) and incongruent (I columns) settings when k are small. This implies that our proposed model utilizes images for translation by learning to extract needed information from visual clues. The interesting part is for a full translation, where scores for the incongruent setting are very close to those of the congruent setting. The reason is that when textual information is enough, visual information becomes not that relevant in some cases.

6.2 How Source-Target Word Order Affects Translation

In wait-k translations, for the En→Ja language pair with different word orders (SVO vs. SOV), some source tokens should be translated before they are presented to the decoder for grammaticality and fluency purposes. Hence, the model also needs to handle such cases well apart from the "usual" order. We hypothesized that MSNMT models, given additional visual information, are able to translate such cases better than SNMT models. Therefore, we investigated how many tokens were correctly translated that are not given as input yet.

First, we quantitatively analyze how well we can translate entities that are not presented from the source yet but should exist in target sentences. To align the source and target entities, we use the entities' annotation attached to both the source and target sentences. Given that annotated entities have the same IDs and tags for both English and Japanese, we can align, calculate, and extract those entities from source and target sentences. If the index of the first token of the aligned target entity is not given as input at timestep k yet, we count them for each k scenario as # total entities (Table 4). For example, in Table 3 a wait-3 model should start translating after a token "rappelling" is presented to the model. And if an ID of the entity of "海 (a body of water)" is in the target sentences but not in the inputted part yet, we count it as an entity that should be translated before being inputted to the model. Similarly, an entity of "断崖 (cliff)" is already presented to the model at timestep 5, so we do not count those entities. If the same entity ID appears more than once in one sentence, we exclude those entities due to the impossibility of alignments. Finally, for each model during decoding, if those entities are included in the model's translation results with a perfect match from pre-calculated # total entities, we consider them as correctly translated.[10]

Table 4 demonstrates the results. k column is to determine how many tokens a model waits before starting translating. Note that k=Full is not included because all entities are given at the time of translation. The reason that the total number of entities that were not inputted yet decreases when k increases (# total entities column) is that more entities are already available for the model for translation. wait-k columns show how many entities were correctly translated by wait-k SNMT and MSNMT models from # total entities for each k scenario. Columns Full show upper-bounds of how many entities can be correctly translated if the models were trained with full sentences for entities from each k. Comparing Full results to wait-k for both SNMT and MSNMT shows that it is hard to correctly translate entities when k is small. Furthermore, comparing wait-k results of SNMT to MSNMT, it can be seen that the smaller value of k, the better MSNMT can handle different source-target word order than SNMT.



(a) A person rappelling a cliff.

(b) Eight men on motorcycles.

Figure 2: Images presented in translation examples (Table 5).

As an example, we sampled sentences and their images from the En→Ja test set (Figure 2) to compare the outputs of our systems. Table 5 lists their translations generated by SNMT (S) and MSNMT (M) models. In the first example, an SNMT model with wait-3 could not predict "海 (sea, a body of water)" which appears at the end of the source sentence and generated an erroneous "岩 (rock)" which is not present neither in source text nor in a corresponding image. Contrarily, the MSNMT model with wait-3 was able to correctly predict "海 (body of water)" even before it was inputted by capturing visual information. When a full sentence is given as an input, MSNMT translated it correctly using more information, unlike SNMT, which translated only from the given text and generated incorrect "登って (climbing)" instead of "降りて (rappelling)". Interestingly, in the second example, the MSNMT model with wait-3 predicted "自転車 (bicycles)" instead of "オートバイ (motorcycles)" at the beginning of the sentence, while the SNMT model with wait-3 was not able to generate any vehicle entities. Also, both MSNMT models with wait-3 and Full correctly captured that there were eight men, whilst both SNMT models incorrectly predicted about one and two men. From these results, we can conclude that visual clues pos-

[10] We can not create # total entities from decoded tokens directly due to unavailability of entity annotations.

t	1	2	3	4	5	6	7	8	9	10	11											
Source	a	person	rappelling	a	cliff	above	a	body	of	water	.

itively impact generated translations where there is still a lack of textual information, especially when we deal with language pairs with different word order.

7 Conclusion

In this paper, we proposed a multimodal simultaneous neural machine translation approach, which takes advantage of visual information as an additional modality to compensate for the shortage of input text information in the simultaneous neural machine translation. We showed that in a `wait-k` setting, our model significantly outperformed its text-only counterpart in situations where only a few input tokens are available to begin translation. We showed the importance of the visual information for simultaneous translation, especially in the low latency setup and for a language pair with word-order differences. We hope that our proposed method can be explored even further for various tasks and datasets.

In this paper, we created a separate model for each value of `wait-k`. However, in future work, we plan to experiment on having a single model for all `k` values (Zheng et al., 2019b). Furthermore, we acknowledge the importance of investigating MSNMT effects on more realistic data (e.g. TED), where the utterance does not necessarily match a shown image while speaking and/or where its context can not be guessed from the shown image.

Acknowledgments

We are immensely grateful to Raj Dabre and Rob van der Goot who provided expertise, support, and insightful comments that significantly improved the manuscript. We would also like to show our gratitude to Desmond Elliot for valuable feedback and paper discussions. We want to thank Ozan Caglayan for pointing out critical bugs in our previous implementation.

Abstract

Context-aware neural machine translation (NMT) is a promising direction to improve the translation quality by making use of the additional context, e.g., document-level translation, or having meta-information. Although there exist various architectures and analyses, the effectiveness of different context-aware NMT models is not well explored yet. This paper analyzes the performance of document-level NMT models on four diverse domains with a varied amount of parallel document-level bilingual data. We conduct a comprehensive set of experiments to investigate the impact of document-level NMT. We find that there is no single best approach to document-level NMT, but rather that different architectures come out on top on different tasks. Looking at task-specific problems, such as pronoun resolution or headline translation, we find improvements in the context-aware systems, even in cases where the corpus-level metrics like BLEU show no significant improvement. We also show that document-level back-translation significantly helps to compensate for the lack of document-level bi-texts.

1 Introduction

Even though machine translation (MT) has greatly improved with the emergence of neural machine translation (NMT) (Sutskever et al., 2014; Bahdanau et al., 2015) and more recently the Transformer architecture (Vaswani et al., 2017), there remain challenges which can not be solved by using sentence-level NMT systems. Among other issues, this includes the problem of inter-sentential anaphora resolution (Guillou et al., 2018) or the consistent translation across a document (Läubli et al., 2018), for which the system inevitably needs document-level context information.

In recent years, many works have focused on changing existing NMT architectures to incorporate context information in the translation process (Tiedemann and Scherrer, 2017; Bawden et al., 2018; Voita et al., 2018). However, often times results are reported only on very specific tasks (most commonly subtitle translation), making it difficult to assess the potential of the different methods in a more general setting. This, together with the fact that big improvements are typically reported on low resource tasks, gives the impression that document-level NMT mostly improves due to regularization rather than from leveraging the additional context information. In this work we want to give a more complete overview of the current state of document-level NMT by comparing various approaches on a variety of different tasks including an application-oriented E-commerce setting. We discuss both, widely used performance metrics, as well as highly task-specific observations.

Another important aspect when talking about document-level NMT is the applicability in "real life" settings. There, when faced with a low resource data scenario, back-translation is an established way of greatly improving system performance (Sennrich et al., 2016a). However, to the best of our knowledge, the effect of back-translation data obtained and used by context-aware models has never been explored before. The main contributions of this paper are summarized below:

- We explore several existing context-aware architectures on four diverse machine translation tasks, consisting of different domains and data quantities.
- We examine the usage of context aware embeddings created by pre-trained monolingual models and study to what extent these embeddings can be simplified.
- We conduct corpus studies and extensive analysis on corpus specific phenomena like pronoun resolution or headline translation to give

Proceedings of the 5th Conference on Machine Translation (WMT), pages 604–616
Online, November 19–20, 2020.

an interpretation of the potential improvements from leveraging context information.

- We study the effects of utilizing document-level monolingual data via back-translation and report significant improvements particularly for document-level NMT systems.

2 Related Works

The discourse- or document-level translation is a long-standing and unsolved topic in the machine translation community (Mitkov, 1999; Carpuat, 2009; Hardmeier, 2014). Although neural machine translation (Sutskever et al., 2014; Bahdanau et al., 2015; Vaswani et al., 2017) has recently become the dominant translation paradigm that provides superior performance, the independence between sentences is still the fundamental assumption taken for granted by most NMT systems. This means, that discourse-level phenomena between sentences such as pronominal reference, consistent lexical choice, and verbal tenses, etc. can not be addressed by these sentence-level NMT systems (Läubli et al., 2018; Guillou et al., 2018). The current NMT approaches tackling inter-sentential discourse phenomena can be roughly categorized into three aspects, augmenting NMT by

- adding source-side context
- including both source- and target-side context
- utilizing source- and/or target-side document-level monolingual data

To include the source-side context, Tiedemann and Scherrer (2017) concatenate consecutive sentences as input to the NMT system, while Jean et al. (2017); Bawden et al. (2018); Zhang et al. (2018) use an additional encoder to extract contextual information from a few previous source-side sentences. These works only consider a local context, including a few previous sentences. Some researches seek to capture the global document context; Wang et al. (2017) summarize the global context from all previous sentences in a document with a pre-trained hierarchical RNN and then use it for updating decoder states. Very recently, Chen et al. (2020) proposed a discourse structure-based encoder that takes account of the discourse structure information of the input document.

For adding additional target-side context, Tiedemann and Scherrer (2017); Agrawal et al. (2018) conduct multi-sentences decoding and observe only a minor improvement. Maruf and Haffari (2018) apply cache-based models to store vector representations for both source- and target-side context. Similarly, Tu et al. (2018) augment their NMT system with an external cache to memorize the translation history. Werlen et al. (2018) integrate two hierarchical attention networks (HAN) (Yang et al., 2016) in the NMT model to take account for source and target context. Maruf et al. (2019) apply a hierarchical attention module on sentences and words in the context to select contextual information that is more relevant to the current sentence.

For incorporating document-level monolingual data from the source language, Zhu et al. (2020) use BERT (Devlin et al., 2019) to model the source-side context and integrate it with the encoder and decoder of the NMT model. Junczys-Dowmunt (2019) share the parameters of a BERT-style encoder trained on monolingual documents with the MT model.

To utilize the document-level monolingual data from the target language, Junczys-Dowmunt (2019) also submit a system that trained on the combination of real and synthetic document-parallel data obtained by back-translation. However, they do not consider document-level back-translation. Voita et al. (2019a) proposed a document-level post-editing system which is trained only using the monolingual document-level corpus.

Recently, there has been a tendency in the community to conclude that the context used in a context-aware MT model works as regularisation or noise generator. Kim et al. (2019) compare several multi-encoders methods and claim that including this additional information can improve translation performance, but it is mostly due to the regularization effect rather than the contextual information. Li et al. (2020) also compare some context-aware architectures by replacing the real context with some random signal and show that random signals can achieve the same level improvement as the real context. However, it should be taken with a grain of salt since solving this task, along with the analysis, is quite challenging. There are many impact factors from the architecture, the data at hand, to the metric being used for evaluation.

One issue that can not be ignored in all discourse-related researches is the problem of evaluation. Since some discourse-level phenomena between sentences appear less frequently, although relevant, there is doubt if the metrics like BLEU score (Papineni et al., 2002) can capture these complex re-

lationships (Le Nagard and Koehn, 2010; Hardmeier and Federico, 2010). To get more insights into the capacities dealing with discourse-level phenomena of their MT models, some researchers use more targeted evaluation scores (Wong et al., 2020), like the Accuracy of Pronoun Translation (APT) Werlen and Popescu-Belis (2017), or they evaluate their systems on some specific test suites that contain more and more complex discourse phenomena (Hardmeier et al., 2015; Guillou et al., 2018; Müller et al., 2018; Voita et al., 2019b).

3 Document-level NMT

In this section, we first describe several commonly used context-aware NMT architectures and highlight the differences among them, largely following the work by Kim et al. (2019). Afterwards, we describe one radical attempt to represent the document-level context in one single embedding vector using BERT (Devlin et al., 2019). Finally, we explain our proposed paradigm to use document-level back-translation in detail. Note that in this work, we consistently use Transformer (Vaswani et al., 2017) as our basic architecture and modify it accordingly.

3.1 Context-Aware Architectures

Given a source sentence in a document to be translated, in order to exploit the source-side context from its previous sentences in the same document, a simple and straightforward technique is to concatenate these contextual sentences with the current source sentence (Tiedemann and Scherrer, 2017; Agrawal et al., 2018). Similarly, if the previous and current target sentences are to be generated together, i.e. $\underline{\mathrm{e}}_1^I = e_1^{I_{\mathrm{pre}}}$ BREAK $e_1^{I_{\mathrm{cur}}}$, then the target-side context can also be considered by the model (Tiedemann and Scherrer, 2017). Two additional special tokens are introduced to indicate the boundary between sentences and the beginning of a document, respectively. In this case, there is no modification of the model architecture itself, as seen in Figure 1.

An alternative way to model the source-side context is via an additional encoder, as shown in Figure 2. The previous sentence f_{pre} is fed into an additional encoder to obtain the hidden representation of the source context sentence $h_{j_{\mathrm{pre}}}^{L-1}$. At the last layer of the encoder, the source representation h_j^{L-1} attends to $h_{j_{\mathrm{pre}}}^{L-1}$ and outputs the combined hidden representation c_j^L (Voita et al., 2018). Then,

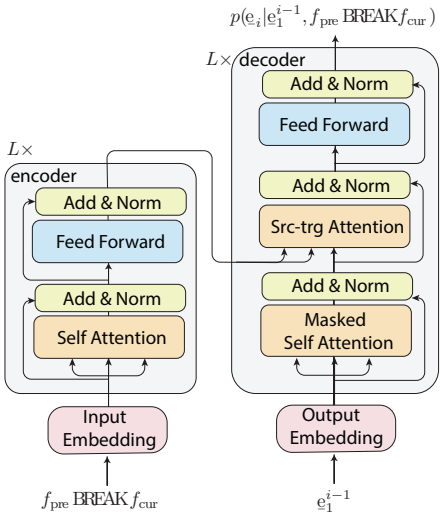

Figure 1: Single Encoder (2to2) approach only considering the one previous source sentence as context.

a gating mechanism (Bawden et al., 2018) between h_j^L and c_j^L is followed:

$$g_j = \sigma(W_g[h_j^L, c_j^L] + b_g) \quad (1)$$

$$o_j = g_i \odot W_s h_j^L + (1 - g_i) \odot W_c c_j^L \quad (2)$$

We refer to this approach as "Multi-Encoders (Out.)".

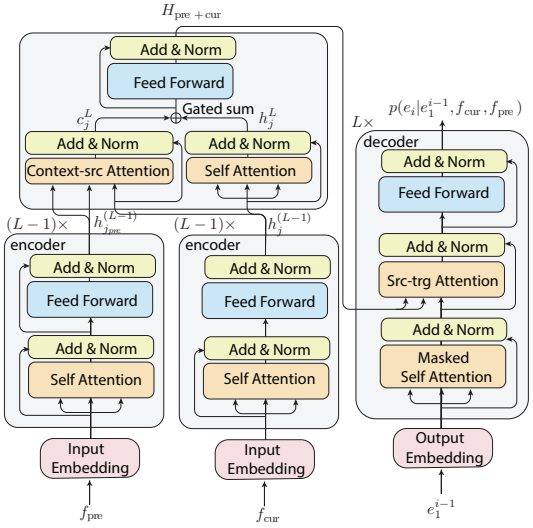

Figure 2: Multi-Encoders Out-side of decoder approach (Out.).

Another way to do the integration is to keep the representation of the current source sentence and the representation of the contexts separate and allow the decoder to have access to the context representations. Figure 3 shows a sequential integration inside of the decoder, where the decoder firstly attends to the current source representation,

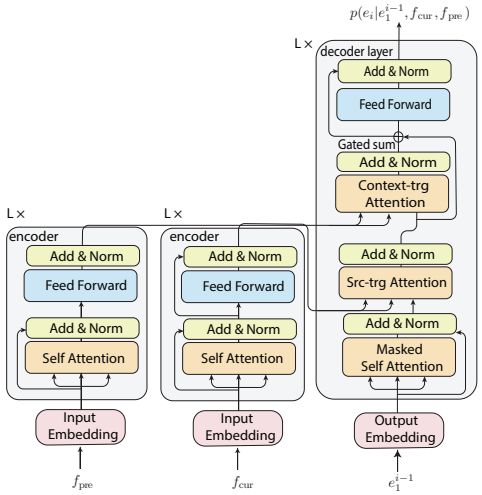

Figure 3: Multi-Encoders followed by attention components Inside of decoder Sequentially (In. Seq.).

then its output attends to the context representation (Zhang et al., 2018). The same gating mechanism as in the Multi-Encoders (Out.) approach is used between the two attention outputs. We refer to this approach that uses multi-encoders followed by attention components inside of decoder sequentially as "Multi-Encoders (In. Seq.)".

Figure 4 shows a parallel integration of the context inside of the decoder, where the decoder attends to the source and context representation in parallel and the outputs of them are combined again using a gating mechanism (Bawden et al., 2018). In this paper, we call this approach using multiple encoders followed by attention components inside the decoder in parallel "Multi-Encoders (In. Par.)".

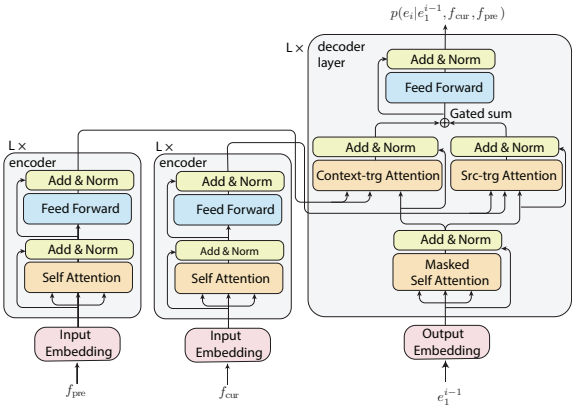

Figure 4: Multi-Encoders followed by attention components Inside of decoder in Parallel (In. Par.).

In addition, we use "WordEmb (In. Par.)" to refer to the approach that only uses word embeddings without any hidden layers to model the context and integrate it following the Multi-Encoders (In. Par.).

Considering that a pre-trained model like ELMo (Peters et al., 2018) or BERT (Devlin et al., 2019) can capture rich representations of the input, it is apparent that one can also use it to model contextual information. Figure 5 shows the BERT-fused model proposed in Zhu et al. (2020), which uses a BERT encoder to obtain the BERT hidden representations H_B on the concatenation of the context sentence f_{pre} and the current source sentence f_{cur}. H_B is further fused into each layer of the encoder

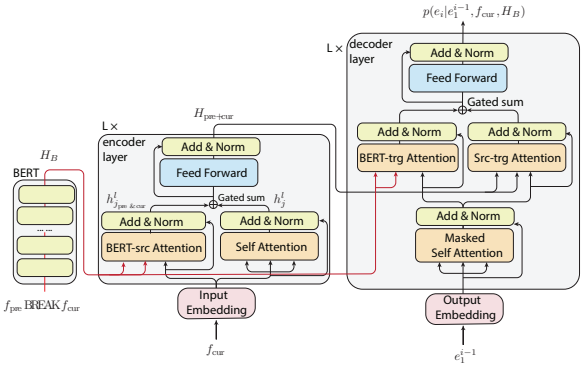

Figure 5: BERT sequence embeddings approach (Zhu et al., 2020).

and decoder of the NMT model using the attention mechanism to obtain the context representation. Instead of using the summation operation like in the original paper, we combine the context representation $h^l_{j_{\text{pre\&cur}}}$ and source representation h^l_j with a gating mechanism on the encoder side. Similar operation for the integration on the decoder side is used. This approach corresponds to the "BERT sequence embeddings (emb.)" approach in our main results in Table 3.

3.2 Single Embedding Vector as Context Representation

The introduction of additional encoders or attention components in the approaches mentioned in Section 3.1 brings a large number of parameters, which is not always ideal. Further, we propose one radical attempt to summarize the document-level context into one single embedding vector. We average the embeddings in the context representation H_B obtained by BERT to obtain one single mean-pooled embedding and then concatenate it with the word embeddings of the current source sentence along time axis (T-axis) or feature axis (F-axis). Besides, for the e-commerce dataset, we also apply a variant of BERT, which we call eBERT, that was

trained with additional e-commerce item titles as supplement in-domain data.

3.3 Document-level Back-translation

While there exist many works showing the improvements of context-aware systems, some major aspects are typically not covered - one of them being back-translation (Sennrich et al., 2016a). Back-translation is an integral part when building the strongest possible systems and is currently the best way to include monolingual data in the training of a NMT system. It uses an inverse, target-to-source, MT model to generate synthetic source sentences given target-side monolingual sentences. There exists a series of works on this topic (Hoang et al., 2018; Burlot and Yvon, 2018; Graça et al., 2019). However, the underlying inverse MT model used so far is mostly on the sentence level.

In this work, we argue that back-translation could be even more crucial when training document-level NMT systems, since even for common language pairs like German-English we have very limited amounts of parallel document-level data while having an abundance of monolingual document-level data. In addition, except for using a sentence-level inverse NMT model, we also introduce a document-level inverse MT model to generate pseudo source documents given monolingual target-side documents. The intuition behind this approach is that we expect the document-level back-translation system to keep more inter-sentential discourse-phenomena in the synthetic source documents. If the back-translation system is merely on the sentence level, some discourse-phenomena, like consistent lexical choices, might not remain in the generated source documents. Losing this potentially large amount of discourse-phenomena is not beneficial for training a context-aware model.

Since there is a large amount of document-level, monolingual in-domain data in the form of the NewsCrawl corpora, we conduct back-translation experiments on the WMT task. Here, we first train a baseline model and a context-aware model on the WMT news-commentary v14 in the reverse direction (De-En). We decide to use Multi-Encoders (In. Par.) as our inverse context-aware model, as it has the best performance on the WMT task. Then we sample 4.8M sentences pairs from news-docs2018 monolingual corpus,[1] which contains 168K documents. Next, we use the inverse NMT models to translate them applying beam search with beam size 5 and concatenate the resulting bilingual synthetic data with the real documents in the news-commentary v14 dataset (En-De). Finally, we compare the performance of a sentence-level baseline (En-De) and a context-aware model, Single Encoder (2to2), on both concatenated corpora. To our knowledge, this is the first attempt to explore the document-level back-translation data systematically (see Section 4.3.5).

4 Experiments

4.1 Datasets

We experiment with various parallel document-level datasets including IWSLT TED talk English-Italian,[2] WMT news-commentary v14 English-German,[3] OpenSubtitles (Lison and Tiedemann, 2016) v2018 English-German[4] and an additional in-house e-commerce English-Chinese dataset. The test sets for the former two are the IWSLT 2017 test set and WMT newstest2018, respectively; for the latter two, we have created the dev and test sets ourselves by doing appropriate splits to the complete dataset.[5] The data statistics of bilingual corpora used for fine-tuning context-aware models are summarized in Table 1. In the IWSLT, WMT and OpenSubtitles datasets, there exists a boundary between documents. We first take them as sentence-level corpora to train the baseline and further fine-tune the context-aware system on them.

The context-aware part of the e-commerce dataset is quite small and distinct from the other tasks: it does not contain documents or talks, but rather sentence-level item descriptions from an e-commerce website. As translation context, we provide the title of the item, instead of preceding sentences. Item descriptions and titles are user-provided, so they may contain ungrammatical sentences, spelling errors, and other noise. We give the title as context on the source-side, and we have reference translations only for the descriptions. In

Table 1: Training/development/test corpora statistics.

order to get a strong baseline, we additionally use a large sentence-level e-commerce dataset consisting of 6M sentence pairs (2.7M in-domain and 3.3M out-of-domain e-commerce) to train the baseline system, and then use it as initialization for fine-tuning on the context-aware e-commerce dataset. This dataset allows us to investigate context-aware NMT in a realistic scenario, in which the majority of training data does not have additional context.

To get a better insight into the model's performance for tackling the pronoun translation, we evaluate our models on two targeted test sets: one is ControPro for OpenSubtitles, the other is a coreference-focused test set for WMT. ControPro is introduced in Müller et al. (2018), which is a contrastive test set extracted from OpenSubtitles with previous sentences as context. The source sentence has the English pronoun *it* and three corresponding German translations containing German counterparts *es*, *sie*, *er*, i.e., one of them is correct, and the other two are incorrect. The evaluation is done by counting the decisions that models rank the correct translation higher than the incorrect translations. In addition to using it in this way, we keep the source and the corresponding correct translation to form a standard test set containing 12K sentence pairs and measure the general translation quality on it.

	ControPro	Coreference
# Sentences	12K	1.1K
# Running words	129K	28K
Avg. sentence length	11	26

Table 2: Two targeted-test sets: ControPro (Müller et al., 2018) and coreference-focused test set extracted from WMT newstest 2008-2019 using NeuralCoref.

To create a targeted test set for WMT, we use an external tool called NeuralCoref[6]. We first apply this external tool to detect the coreference resolution in two consecutive sentences from newstest2008-2019, and then only keep the sentences where the coreference is resolved intersententially. This results in a targeted test set containing more inter-sentential discourse phenomena. The detailed statistics of these two targeted test sets are given in Table 2.

All language pairs are preprocessed with the Moses tokenizer[7] except for the Chinese corpus which is preprocessed with the chinese text segmentation tool "jieba"[8]. We apply byte pair encoding (Sennrich et al., 2016b) with 32k merge operations jointly for source and target languages.

4.2 Experimental setting

All models are implemented in open-source toolkit OpenNMT (Klein et al., 2017). For the sentence-level baseline system, we follow a 6-layer base Transformer model (Vaswani et al., 2017) and set the hidden size and embedding size as 512 and the dimension of the feed-forward layer as 2048. We use 8 heads for multi-head attention. For our context-aware models, we extend baseline system to include additional encoder with the same setting. In training, we use Adam optimizer (Kingma and Ba, 2014) or its variant Lazy Adam Optimizer for optimization and follow the learning rate schedule described in (Vaswani et al., 2017). The learning rate scale factor and warm-up steps are different for different datasets. In all our experiments, we share word embeddings over the source and the context. The context encoders are also initialized by the encoder of the sentence-level baseline.

For automatic evaluation, we report case-sensitive sacreBLEU score (Post, 2018) for all corpora except for e-commerce, on which the evaluation is done in Chinese character-level with case-insensitive sacreBLEU.

4.3 Analysis

4.3.1 Performance in Terms of BLEU

Table 3 shows the corpus-level BLEU-scores of all architectures on different tasks. For the baseline as well as the "source-side-only" systems we get similar results to Kim et al. (2019) on the IWSLT

Table 3: Comparison of document-level architectures on different tasks. "Type" indicates whether the context used is from source(s)- or target(t)-side or if additional monolingual(m) data is included. "e" or "d" following the name of BERT sequence emb. approach indicates whether the context representation is fused on the encoder or decoder.

and WMT tasks, with Multi-Encoders (In. Par.) being the strongest architecture. For the e-commerce data, Multi-Encoders (In. Seq.) performs slightly better. Interestingly, with these architectures we do not see improvements on the much larger OpenSubtitles corpus. This seems to confirm the suggestion of Kim et al. (2019) that these architectures work more as a regularization which is much more important for low resource tasks.

The Single Encoder (2to2) results in an improvement on all tasks excluding the e-commerce task, for which the method is not applicable due to the lack of target translation of the context (titles). The improvements on the OpenSubtitles test set are comparable to what has been reported in the literature (Tiedemann and Scherrer, 2017) while the improvements on the other tasks are a bit smaller. We notice that with this architecture, the improvements increase with decreasing average sentence length, which makes sense since it is known that the Transformer struggles with long input sequences (Rosendahl et al., 2019). This seems also to be indicated by the deteriorating performance of the Single Encoder (3to1) system, which confirms the findings of Agrawal et al. (2018).

Including context information through BERT sequence embeddings improves the performance on IWSLT, WMT and the e-commerce tasks but not on OpenSubtitles. The pre-trained BERT brings more (monolingual) data, which should again help primarily on the low resource tasks. Contrary to the before mentioned approaches, the BERT single embedding approach does not significantly increase the number of free parameters, but it only works on the e-commerce task in our experiments. This finding as well as the discrepancy between concatenating along the time or feature axis is discussed in detail in Section 4.3.2.

While these findings are consistent with previous works, we find it to be insufficient to just rely on corpus-level BLEU scores to come to a conclusion about the usefulness of these approaches. In the subsequent sections we discuss specific aspects of the translations which might be easily overlooked. Furthermore we investigate the utilization of back-translation (Sennrich et al., 2016a) for document-level systems, in an effort to compare these architectures in a more "real-life" setting where back-translation is almost always used.

4.3.2 Including BERT

When looking at the results in Table 3, we see that using the embeddings produced by BERT yields some decent improvements on all tasks except for OpenSubtitles. This might indicate that the improvements - at least in parts - come from the usage of additional data when training the BERT model rather than from an improved context representation. A drawback when using the BERT system combination is the introduction of many additional parameters and calculations. This can be drasti-

System	IWSLT		WMT		E-commerce data	
	# tokens	BLEU[%]	# tokens	BLEU[%]	# tokens	BLEU[%]
Reference	19931	-	64276	-	40149	-
Baseline	-226	31.6	+1117	28.4	-2672	33.7
BERT single emb. (T-axis)	-66	31.7	+879	28.7	-2174	34.5
Random emb. (T-axis)	+19	31.5	+1557	28.7	-2177	34.7

Table 4: Using different vectors for context representation. For the reference, the number of tokens stands for the total number of target tokens in the reference. In all consecutive lines, the number stands for the difference in the number of tokens compared to the reference.

cally reduced when using a single vector extracted from BERT as described in Section 3.2. However, the results of this approach are not significantly outperforming the baseline system on any tasks except for the e-commerce data.

Surprisingly, the eBERT does yield no further improvement over the BERT variant and the concatenation along the F-axis leads to a significant degradation in performance. These two factors lead us to believe that the context information is not the decisive factor but something else. To investigate this, we replaced the BERT-generated context vector with a random vector and compared the resulting BLEU scores which are shown in Table 4.

Depicted in this table are the BLEU score as well as the number of tokens in the respective hypothesis for the IWSLT, WMT and e-commerce tasks. For replacing the real context vector we create the random vector by sampling from the uniform distribution. Looking at the results, we see that our assumption is correct: the variant using a random vector yields the same improvements as the real context vector on the e-commerce task - even though it inhabits no relevant context information.

The reason behind this becomes clear when comparing the number of tokens produced in the hypotheses: On the e-commerce task we have a noticeable problem with under translation. We argue that by increasing the length of the input sequence we inevitably increase the length of the output, leading to a longer hypothesis and consequently to a smaller brevity penalty when calculating BLEU. This effect is not present for the other tasks at hand, since there we do not have a significant effect of under translation. We note that similar results were obtained very recently by Li et al. (2020), who also see improvements when replacing the context signal with random noise. However, we conclude that the underlying effect is a different one, since we see no improvements when concatenating along the feature axis or when evaluating on a different task. In conclusion, we argue that the improvements seen by using the BERT-embeddings for context information rather comes from additional data and other effects discussed in this section, rather than from the usage of actual context information.

4.3.3 Better Headline Translation using Context

In this section we discuss another unexpected effect of using context information in the translation, namely giving the system additional information about the nature of the input. In the WMT task, both the train and test data consist of articles composed of a headline followed by a body of text, consisting of several sentences. This means the only time the system has no context information at hand, is when translating the headline of an article. We argue that the system can in fact use this information to distinguish whether the input sequence at hand is a headline or a real sentence and act accordingly. Since a headline has a very distinguishable style compared with a complete sentence, this should lead to improvements in the translation quality. To examine this hypothesis, we separate the WMT test set into two parts: One consisting only of headlines and the other one consisting only of body of texts. We then evaluate the baseline system and our strongest document-level system (Multi-Encoders (In. Par.) for WMT) separately on both sets, The results can be seen in Table 5.

We see that the translations of both sets are improved when using the document-level setup. However, the improvement on the headlines is much larger (+4.5% BLEU) than on the body of text (+1.7% BLEU). When manually checking the hypotheses, we find that the baseline system often times tries to translate a headline as a "complete" sentence (e.g. including a verb) while the document level system translates these in a much more consistent style. This observation coincides with the fact

System	BLEU[%]
Baseline	28.4
Doc-level	**30.1**
Baseline_headlines	19.9
Doc-level_headlines	**24.4**
Baseline_newsbody	28.5
Doc-level_newsbody	**30.2**

Table 5: System performance in terms of BLEU on headlines vs body of text for the WMT test set. The document-level system is Multi-Encoders (In. Par.).

that the baseline system shows severe signs of over-translation (on average 14.9% more tokens than the reference) and the document-level system does not (-1.2%). We note that this effect is not responsible for the overall improvement in the corpus-level BLEU, since the ratio of headlines to text is very small (3.9%). This becomes clear when comparing the improvements on the body of text vs the complete test set - which is equal. We conclude that this is another instance where the context improves the translation quality even if it is not immediately obvious.

4.3.4 Pronoun Resolution

Testing the correct translation of pronouns is an established method to compare the context-awareness of document-level machine translation systems (Guillou et al., 2016; Jean et al., 2017; Bawden et al., 2018; Voita et al., 2018; Werlen et al., 2018; Wong et al., 2020). It can be argued that the ability of correctly translating inter-sentential pronouns not only depends on the architecture at hand but also on the data which the system is trained on. We decide to test the pronoun resolution capabilities of our systems in two different ways: First we are using an automatic metric for the accuracy of pronoun translation (APT) (Werlen and Popescu-Belis, 2017) and second we use two targeted test sets described in Section 4.1. The results on OpenSubtitles and WMT can be found in Table 6.

We calculate BLEU and APT scores on both the OpenSubtitles test set and ControPro test set (without contrastive translations) (Müller et al., 2018). Furthermore we calculate the resolution accuracy on ControPro (with contrastive translations). We compare the sentence-level baseline system with the best performing document-level system on this task - Single Encoder (2to2) as well as the Single Encoder (2to1) system. Even though the latter does not significantly improve over the baseline on the OpenSubtitles test set, we find a significant increase in pronoun translation accuracy in terms of both evaluation methods. The Single Encoder (2to2) system is even stronger in terms of pronoun translation, outperforming the baseline system by an impressive 33.9% absolute accuracy on the targeted test set. When calculating BLEU on ControPro, the gap between the baseline and the document-level systems becomes significantly larger. The BLEU scores for the Single Encoder (2to2) and the Single Encoder (2to1) systems are equal.

When looking at the APT scores on WMT test set, the context-aware system does not provide much improvement. We assume the reason is that the portion of the potential improvement regarding inter-sentential pronoun resolution is quite small, having looked through this test set. The increased gap of APT score between the baseline system and the context-aware system on the coreference-focused test set confirms this assumption, as there are more inter-sentential coreference phenomena in this targeted test set. Note that the BLEU score gaps between the baseline and context-aware systems on both test sets are almost the same.

All in all we can conclude that in this case the context information is helpful for a better translation, even though the effect might not be visible when just looking at corpus level BLEU.

4.3.5 Document-level Back-translation

When dealing with document-level monolingual data, the question arises, whether a sentence-level back-translation system is sufficient to generate the synthetic data. In this section, we investigate the effect of the sentence-level back-translation data and document-level back-translation data on the baseline system as well as a context-aware system. The sentence-level baseline and context-aware model used to generate synthetic documents have 28.3% BLEU and 29.7% BLEU on the test set, respectively. The performance of the resulting En-De systems are summarized in Table 7.

When using the synthetic data generated by the sentence-level system we see a huge increase in performance for both systems (+5.5% BLEU for the sentence-level system and +7.2% BLEU for the document-level system). A large increase in performance is to be expected since we increase the amount of data by roughly a factor of 8. The systems trained on the synthetic data generated by the document-level system show even further improvements (+1.6% BLEU for the sentence-level

System	OpenSubtitles		ControPro			WMT		Coreference test	
	BLEU	APT	BLEU	APT	corr.	BLEU	APT	BLEU	APT
Baseline	37.3	52.8	30.5	35.4	48.7	28.4	40.6	18.9	24.0

Doc-level	Sent-level	35.5
	Doc-level	**36.5**

Table 7: Including back-translation data to the WMT task. The architecture of the document-level system is the Single Encoder (2to2) approach.

system and +0.4% BLEU for the document-level system). This might be in part due to the fact that the document-level back-translation system is stronger than the sentence-level one.

A very interesting observation is that the document-level system profits significantly more from the synthetic data in both scenarios. This contradicts the proposition that document-level architectures function mainly as a form of regularization for low resource data-settings. To the contrary we see an especially large gap in the case where we use only the sentence-level back-translation system for synthetic data generation. We argue that the reason for this is, that the document-level system is more capable in recovering from errors made during the back-translation due to the context information. For example a wrongly translated pronoun on the source side will definitely lead the sentence-level system astray, but the document-level one might still recover when the context is correct. This assumptions is also supported by the fact that the gap between sentence-level and document-level system gets smaller when using synthetic data generated by the document-level system, since we assume less such errors get made by this system.

5 Conclusion

In this work, we give a comprehensive comparison of current approaches to document-level NMT. To draw meaningful conclusions, we report results for standard NMT metrics on four diverse tasks - differing in the domain and the data size. We find that there is no single best approach to document-level NMT, but rather that different architectures work the best on various tasks. Looking at task-specific problems, such as pronoun resolution or headline translation, we find improvements in the context-aware systems, which is not visible in the corpus-level metric scores.

We also investigate methods to include document-level monolingual data on both source (using pre-trained embeddings) and target (using back-translation) sides. We argue that the performance improvements from the pre-trained encoder predominantly come from increased training data and other task-specific phenomena unrelated to actual context information utilization. Regarding back-translation, we find that document-level systems seem to benefit more from synthetically generated data than their sentence-level counterparts. We discuss that this is because document-level systems are more robust to sentence-level noise.

We plan to expand our experiments to incorporate document-level monolingual data on both source and target sides. This makes sense just by looking at the data conditions of almost every task: document-level parallel data is scarce, but document-level monolingual data is abundant.

Abstract

Domain adaptation is an old and vexing problem for machine translation systems. The most common and successful approach to supervised adaptation is to fine-tune a baseline system with in-domain parallel data. Standard fine-tuning however modifies all the network parameters, which makes this approach computationally costly and prone to overfitting. A recent, lightweight approach, instead augments a baseline model with supplementary (small) adapter layers, keeping the rest of the model unchanged. This has the additional merit to leave the baseline model intact and adaptable to multiple domains. In this paper, we conduct a thorough analysis of the adapter model in the context of a multidomain machine translation task. We contrast multiple implementations of this idea using two language pairs. Our main conclusions are that residual adapters provide a fast and cheap method for supervised multi-domain adaptation; our two variants prove as effective as the original adapter model and open perspective to also make adapted models more robust to label domain errors.

1 Introduction

Owing to multiple improvements, Neural Machine Translation (NMT) (Kalchbrenner and Blunsom, 2013; Sutskever et al., 2014; Bahdanau et al., 2015; Vaswani et al., 2017) nowadays delivers useful outputs for many language pairs. However, as many deep learning models, NMT systems need to be trained with sufficiently large amounts of data to reach their best performance. Therefore, the quality of the translation of NMT models is still limited in low-resource language or domain conditions (Duh et al., 2013; Zoph et al., 2016; Koehn and Knowles, 2017). While many approaches have been proposed to improve the quality of NMT models in low-resource domains (see the recent survey of Chu and Wang (2018)), full fine-tuning (Luong and Manning, 2015; Neubig and Hu, 2018) of a generic baseline model remains the dominant supervised approach when adapting NMT models to specific domains.

Under this view, building adapted systems is a two-step process: (a) one first trains NMT with the largest possible parallel corpora, aggregating texts from multiple, heterogeneous sources; (b) assuming that in-domain parallel documents are available for the domain of interest, one then adapts the pre-trained model by resuming training with the sole in-domain corpus. It is a conjecture that the pretrained model constitutes a better initialization than a random one, especially when adaptation data is scarce. Indeed, studies of transfer learning for NMT such as Artetxe et al. (2020); Aji et al. (2020) have confirmed this claim in extensive experiments. Full fine-tuning, that adapts all the parameters of a baseline model usually significantly improves the quality of the NMT for the chosen domain. However, it also yields large losses in translation quality for other domains, a phenomenon referred to as "catastrophic forgetting" in the neural network literature (McCloskey and Cohen, 1989). Therefore, a fully fine-tuned model is *only useful to one target domain*. As the number of domains to handle grows, training, and maintaining a separate model for each task can quickly become tedious and resource-expensive.

Several recent studies (e.g. (Vilar, 2018; Wuebker et al., 2018; Michel and Neubig, 2018; Bapna and Firat, 2019)) have proposed more lightweight schemes to perform domain adaptation, while also preserving the value of pre-trained models. Our main inspiration is the latter work, whose proposal relies on small *adapter components* that are plugged in each hidden layer. These adapters are trained only with the in-domain data, keeping the pre-trained model frozen. Because these additional

Proceedings of the 5th Conference on Machine Translation (WMT), pages 617–628
Online, November 19–20, 2020.

adapters are very small compared to the size of the baseline model, their use significantly reduces the cost of training and maintaining fine-tuned models, while delivering a performance that remains close to that of full fine-tuning.

In this paper, we would like to extend this architecture to improve NMT in several settings that still challenge automatic translation, such as translating texts from multiple topics, genre, or domains, in the face of unbalanced data distributions. Furthermore, as the notion of "domains" is not always well established, another practical setting is the translation of texts mixing several topics/domains. An additional requirement is to translate texts from domains unseen in training, based only on the unadapted system, which should then be made as strong as possible.

In this context, our main contribution is a thorough experimental study of the use of residual adapters for multi-domain translation. We notably explore ways to adjust and/or regularize adapter modules to handle situations where the adaptation data is very small. We also propose and contrast two new variants of the residual architecture: in the first one (*highway residual adapters*), adaptation still affects each layer of the architecture, but its effect is delayed till the last layer, thus making the architecture more modular and adaptive; our second variant (*gated residual adapters*) exploits this modularity and enables us to explore ways to improve performance in the face of train-test data mismatch. We experiment with two language pairs and report results that illustrate the flexibility and effectiveness of these architectures.

2 Residual adapters

In this section, we describe the basic version of the residual adapter architectures (Houlsby et al., 2019; Bapna and Firat, 2019), as well as two novel variants of this model.

2.1 Basic architecture

2.1.1 The computation of adapter layers

Our reference architecture is the Transformer model of Vaswani et al. (2017), which we assume contains a stack of layers both on the encoder and the decoder sides. Each layer contains two subparts, an attention layer, and a dense layer. Details vary from one implementation to another, we simply contend here that each layer $i \in \{1 \dots L\}$ (in the encoder or the decoder) computes a transform of a fixed-length sequence of d-dimensional input vectors h^i into a sequence of output vectors h^{i+1} as follows ($\mathbf{LN}$ denotes the (sub)layer normalization, $\mathbf{ReLU}$ is the "rectified linear unit" operator):

$$
\begin{aligned}
h_0^i &= \mathbf{LN}(h^i) \\
h_1^i &= \mathbf{W}_{db}^i h_0^i + a_1^i \\
h_2^i &= \mathbf{ReLU}(h_1^i) \\
h_3^i &= \mathbf{W}_{bd}^i h_2^i + a_2^i \\
\bar{h}^i &= h_3^i + h^i.
\end{aligned}
$$

Overall, the i^{th} adapter is thus parameterized by matrices $\mathbf{W}_{db}^i \in \mathbb{R}^{d \times b}$,$\mathbf{W}_{bd}^i \in \mathbb{R}^{b \times d}$, bias vectors $b_1^i \in \mathbb{R}^b$, $b_2^i \in \mathbb{R}^d$, with b the dimension of the adapter . For the sake of brevity, we will simply denote $h_3^i = \text{ADAP}^{(i)}(h^i)$, and $\theta_{\text{ADAP}^{(i)}}$ the corresponding set of parameters.

The "adapted" hidden vectors $\bar{h}^i_{1 \le i \le L-1}$, where L is the number of layers, will then be the input of the $(i+1)^{\text{th}}$ layer; $\bar{h}^L$ is passed to the decoder if it belongs to the encoder side, or is the input of output layer if it belongs to the decoder side. Note that zeroing out all adapters enables us to recover the basic Transformer, with $\bar{h}^i = h^i$ for all i.

In the experiments of Section 3, we use $2 \times L = 12$ residual adapters, one for each of the $L = 6$ attention layers of the encoder and similarly for the decoder.[1]

2.1.2 Design space and variants

This general architecture leaves open many design choices pertaining to the details of the network organization, the training procedure, and the corresponding objective function.

The first question is the number of adapter layers. While in principle, all Transformer layers can be subject to adaptation, it is nonetheless worthwhile to consider simpler adaptation schemes, which would only alter a limited number of layers. Such strategy might be especially relevant when the training data contains very small domains, as in the experiments of Section 3, and for which a complete adaptation may not be necessary or/and or prone to overfitting. Likewise, it might be meaningful to explore ways to share subsets of adapters across domains. This, in turn, raises the issue of which layer(s) to adapt, a question that can be approached in the light of recent analyses of Transformers models, which conjecture that the higher layers encode

[1] In the decoder, the stack of self-attention and cross encoder-decoder attention only counts as one attention layer and only corresponds to one residual adapter.

global patterns with a more "semantic" interpretation, while the lower layers encode local patterns akin to morpho-syntactic information (Raganato and Tiedemann, 2018).

A related question concerns the regularization of adapter layers to mitigate overfitting. Reducing the number of adapters, or their dimensions, is simple, but such choices are difficult to optimize numerically – an issue that becomes important as the number of domain grows. Less naive alternatives can also be entertained, such as applying weight decay or layer regularization to the adapter. Implementing these requires to modify the objective function in a way that still allows for a smooth optimization problem. For instance, weight decay applies a penalization on the weights of the adapters, complementing the cross-entropy term with a function of the norm of the parameters:

$$\bar{L} = \frac{1}{\#(x,y)} \sum_{x,y} (-\log(P(y|x))) + \lambda \sum_{i \in \{1,..,6\} \otimes \{enc,dec\}} \|\theta_{\mathrm{ADAP}^{(i)}}\|_2$$

An alternative scheme is *layer regularization*, which penalizes the output of the adapters, corresponding to the following objective:

$$\bar{L} = \frac{1}{\#(x,y)} \sum_{x,y} (-\log(P(y|x)) + \lambda \sum_{i \in \{1,..,6\} \otimes \{enc,dec\}} \|\mathrm{ADAP}^{(i)}(h_i(x,y))\|_2)$$

Finally, another independent design choice relates to the training strategy for adapters. A first option is to generalize supervised domain adaptation to multi-domain adaptation and to proceed in two steps: (a) train a generic model with all the available data; (b) train each adapter layer with domain-specific data, keeping the generic model parameters unchanged. Another strategy is to adopt the view of Dredze and Crammer (2008), where the multi-domain setting is viewed as an instance of multi-task learning (Caruana, 1997) with each domain corresponding to a specific task. This suggests training all the parameters from scratch, as we would do in a multi-task mode. The generic parameters will still depend on all the available data, while each adapter will only be trained with the corresponding in-domain data.

2.2 Highway Residual Adapters

In the basic architecture described in Section 2.1, the computation performed by lower level layers will impact all the subsequent layers. In this section, we introduce an alternative implementation of the same idea, which however delays the adaptation of each layer to the last layer (of the encoder or the decoder) as depicted on Figure 1. While the basic architecture performs adaptation in sequence, we propose here to perform it in parallel. In this version, only the last hidden vector of the encoder (decoder) is thus modified according to:

$$\bar{h}^L = h^L + \sum_{1 \le i \le L} ADAP^i(h^i) \qquad (1)$$

One obvious benefit of this variant is that it allows us to reuse the hidden vectors h^i of all hidden layers when computing an adapted output for several domains during the inference. In this situation, the forward step needs only to compute the hidden vectors h^i once for the inner encoder layers, before an adapted sequence of vectors is computed at the topmost layer. Therefore, we can fine-tune the model to multiple domains at once without recomputing h^i. This variant also opens the way to more parameter sharing across adapters, a perspective that we will not explore further in this work. Instead, we use it to develop a second variation of the adapter model, that is presented in the next section.

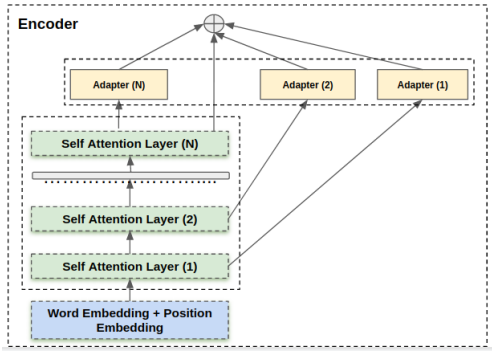

Figure 1: Highway residual adapter network

2.3 Gated Residual Adapters

The basic architecture presented above rests on a rather simplistic view of "domains" as made of well-separated and unrelated pieces of texts that are processed independently during adaptation. Likewise, when translating test documents, one needs to choose between either using one specific domain-adapted model or resorting to the generic model. In

this context, using wrong domain labels can have a strong (negative) effect on translation performance.

Therefore, we would like to design a version of residual adapters that is more robust to such domain errors. This variant, called the *gated residual adapter model*, relies on the training of a supplementary component that will help decide whether to activate, on a word per word basis, a given residual layer and to regulate the strength of this activation. To this end, we extend the highway version of residual adapters as follows.

Formally, we replace the adapter computation of equation (1) and take the adapted hidden (topmost) layer to be computed as (this is for domain k):

$$\bar{h}^L = h^L + \sum_{1 \leq i \leq L} \text{ADAP}_k^i(h^i) \odot z_k(h^L), \quad (2)$$

where the scalar $z_k(h^L[t]) \in [0, 1]$ measures the relatedness of the t^{th} word w_t to domain k. The more likely w_t is in domain k, the larger $z_k(h^L[t])$ should be; conversely, for words[2] that are not typical of any domain k (eg. function words), adaptation is minimum and the corresponding adapted encoder output ($\bar{h}^L[t]$) will remain close to the output of the generic model ($h^L[t]$). In our implementation, we incorporate two domain classifiers on top of the encoder and the decoder, that take the last hidden layer of the encoder (resp. decoder) as input and use the posterior probability $P(k|h^L[t])$ of domain k as the value for $z_k(h^L[t])$.

Training gated residual adapters thus comprises three steps, instead of two for the baseline version:

1. learn a generic model with mixed corpora from multiple domains.

2. train a domain classifier on top of the encoder and decoder; during this step, the parameters of the generic model are frozen. This model computes the posterior domain probability $P(k|h^L[t])$ for each word w_t, based on the representation computed by the last layer.

3. train the parameters of adapters with in-domain data separately for each domain, while freezing all the other parameters.

[2]The term "word" is employed here by mere convenience, as systems only manipulate sub-lexical BPE units; furthermore, the values of the hidden representations h^i at position t depend upon all the other positions in the sentence.

3 Experimental settings

3.1 Data and metrics

We perform our experiments with two translation pairs involving multiple domains: English-French (En→Fr) and English-German (En→De). For the former pair, we use texts[3] initially from 6 domains, corresponding to the following data sources: the UFAL Medical corpus V1.0 (MED)[4], the European Central Bank corpus (BANK) (Tiedemann, 2012); The JRC-Acquis Communautaire corpus (LAW) (Steinberger et al., 2006), documentations for KDE, Ubuntu, GNOME and PHP from Opus collection (Tiedemann, 2009), collectively merged in a IT-domain, Ted Talks (TALK) (Cettolo et al., 2012), and the Koran (REL). Complementary experiments also use v12 of the News Commentary corpus (NEWS). Corpus statistics are in Table 1.

En→De is a much larger task, for which we use corpora distributed for the News task of WMT20[5] including: European Central Bank corpus (BANK), European Economic and Social Committee corpus (ECO), European Medicines Agency corpus (MED)[6], Press Release Database of European Commission corpus, News Commentary v15 corpus, Common Crawl corpus (NEWS), Europarl v10 (GOV), Tilde MODEL - czechtourism (TOUR)[7], Paracrawl and Wikipedia Matrix (WEB). Statistics are in Table 2.

We randomly select in each corpus a development and a test set of 1,000 lines each and keep the rest for training.[8] Development sets help choose the best model according to the average BLEU score (Papineni et al., 2002).[9]

3.2 Baseline architectures

Using Transformers (Vaswani et al., 2017) implemented in OpenNMT-tf[10] (Klein et al., 2017), we train the following baselines:

- a generic model trained on a concatenation of all corpora, denoted **Mixed**;

[3]Most corpora are available from the Opus web site: http://opus.nlpl.eu

[4]https://ufal.mff.cuni.cz/ufal_medical_corpus

MED	LAW	BANK	IT	TALK	REL	NEWS
2609 (0.68)	190 (0.05)	501 (0.13)	270 (0.07)	160 (0.04)	130 (0.03)	260 (0)

Table 1: Corpora statistics for En→Fr : number of parallel lines ($\times 10^3$) and proportion in the basic domain mixture (which does not include the NEWS domain). MED is the largest domain, containing almost 70% of the sentences, while REL is the smallest, with only 3% of the data.

BANK	ECO	MED	GOV	NEWS	TOUR	WEB
4 (0.00022)	2857 (0.15)	347 (0.018)	1828 (0.095)	3696 (0.19)	7 (0.00039)	10473 (0.54)

Table 2: Corpora statistics for En→De: number of parallel lines ($\times 10^3$) and proportion in the basic domain mixture. WEB is the largest domain, containing about 54% of the sentences, while BANK and TOUR are very small.

- a fine-tuned model (Luong and Manning, 2015; Freitag and Al-Onaizan, 2016), based on the **Mixed** system, further trained on each domain with early stopping when the development BLEU score stops increasing during 3 consecutive epochs.

For all En→Fr models, we set the embeddings size and the hidden layers size to 512. Transformers use multi-head attention with 8 heads in each of the 6 layers; the inner feedforward layer contains 2,048 cells. Residual adapters additionally use an adaptation block in each layer, composed of a 2-layer perceptron, with an inner ReLU activation function operating on normalized entries of dimension $b = 1024$. Bapna and Firat (2019) showed that the performance of adapted models increases with respect to the size of the inner dimension and obtained performance close to the full fine-tuned model with $b = 1024$, which is twice as large as the dimension of a Transformer layer. We used the same setting in our experiments.

Training uses a batch size of 12,288 tokens; optimization uses Adam with parameters $\beta_1 = 0.9$, $\beta_2 = 0.98$ and Noam decay ($warmup\_steps = 4,000$), and a dropout rate of 0.1 for all layers. For the **Mixed** model, we use an initial learning rate of 1.0 and take the concatenation of the validation sets of 6 domains for development. In the fine-tuning experiments, we continue training using **Mixed** as starting point, using the same learning rate schedule, and continuing the incrementation of the number of steps. In the multi-task training, we use the same learning rate schedule as for **Mixed**: for each iteration, we sample a domain a probability proportional to its size; we then sample a batch of 12,288 tokens that is used to update the shared parameters and the parameters of the corresponding adapter.

Models for En→De are larger and rely on embeddings as well as hidden layers of size 1024; each Transformers layer contains 16 attention heads; the inner feedforward layer contains 4,096 cells. Adapter modules have the same architecture as for the other language pair, except for their size, which is doubled ($b = 2,048$).

3.3 Multi-domain systems

In this section, we evaluate several proposals from the literature on multi-domain adaptation and compare them to full fine-tuning on the one hand, and to two variants of the residual adapter architecture on the other hand. The reference methods included in our experiments are the following:

- a system using "domain control" (Kobus et al., 2017). In this approach, domain information is introduced either as an additional token for each source sentence (**DC-Tag**) or in the form of a supplementary feature for each word (**DC-Feat**);

- a system using lexicalized domain representations (Pham et al., 2019): word embeddings are composed of a generic and a domain-specific part (**LDR**);

- the three proposals of Britz et al. (2017). **TTM** is a feature-based approach where the domain tag is introduced as an extra word *on the target side*. The training uses reference tags and inference is performed with predicted tags, just like for regular target words. **DM** is a multi-task learner where a domain classifier is trained on top of the MT encoder, so as to make it aware of domain differences; **ADM** is the adversarial version of **DM**, pushing the encoder towards learning domain-independent source representations. These methods only use domain labels in training.

Table 3: Translation performance of various multi-domain MT systems (En→Fr) compared to variants of the residual adapter models.

The two variants of the residual adapter model included in this first round of experiment have been presented in Section 2.1: **Res-Adap** is the multi-domain version of the approach of Bapna and Firat (2019) based on a two-step training procedure; while **Res-Adap-MT** is the "multi-task" version, where the parameters of the generic model and of the adapters are jointly learned from scratch. We also report results for the same system, using the the parameters of the **Mixed** model as initialization (**Res-Adap-MT**$^+$).[11]

Because of the limit of our computational resources, we restrict the experiments in this section to the En→Fr task. Results are in Table 3.

These results first show that full fine-tuning outperforms all other methods for the in-domain test sets. However, **Res-Adap** is able to reduce the gap with this approach for several domains, showing the effectiveness of residual adapters. The "multi-task" variant is slightly less effective in our experiments than the basic version, where optimization is performed in two steps. As it turns out, using residual adapters proves here better on average than the other reference multi-domain systems; it is also much better than the generic system for translating data from known domains, outperforming the **Mixed** system by more than 4 BLEU points in average. Gains are especially large for small domains such as LAW and REL.

Comparing training schemes (**Res-Adap** vs **Res-Adap-MT** vs **Res-Adap-MT**$^+$) suggests that the simultaneous learning of all parameters is detrimental to performance in our settings: we see that the 2-step procedure implemented in **Res-Adap** always yields the best scores, even when **Res-Adap-MT** is initialized with good parameter values . This may be because in this setting, the adapters have access to a stable version of the generic system. The last line (Res-Adap-MT (gen)) gives the results for a **Res-Adap-MT** trained system in which we cancel the adapter in inference - comparing this to **Mixed** shows how differently the generic parts of these two systems behave.

3.4 Varying the positions and number of residual adapters

Tables 4-5 report BLEU scores for 6 domains in each language pair: MED,LAW,BANK,TALK,IT and REL for En→Fr; GOV, ECO, TOUR, BANK, MED and NEWS for En→De. We first see that for the latter direction, the basic version **Res-Adap** also outperforms the **mixed** baseline on average, with large gains for the small domains TOUR, BANK and comparable results for the other domains.

By varying the number and position of residual adapters (see Section 2.1), we then contrast several implementations. Because the set of possible configurations is large, we only perform experiments for layers $i = 2, 4, 6$ (both for the encoder and decoder). Two settings are considered: keeping just one adapter or keeping the three. The trend is the same for the two language directions: suppressing adapters always hurts the overall performance, albeit by a small margin: having six adapters is better than three, which is better than keeping only one. With only one adapter active, we observe small,

[11] This system also includes a layer dropout policy that cancels adapter layers with probability 0.5

insignificant changes in performance when varying the adapter's depth.

3.5 Regularizing fine-tuning

The translation from English into German includes two domains (TOUR and BANK) that are extremely small and account only for a very small fraction of the training data (respectively for 0.039% and 0.022% of the total number of sentences). Fine-tuning on these domains can lead to serious overfitting. We assess two well-known regularization techniques for adapter modules, that could help mitigate this problem: weight decay and layer regularization.

For each method, the optimal hyper-parameter λ (weight decay or layer regularization coefficient, see Section 2.1.2) are chosen by grid search in a small set of values ($\{10^{-3}, 10^{-4}, 10^{-5}\}$).

Results in Tables 4 and 5 show that regularizing the adapter model can positively impact the test performance for the smallest domains (this is especially clear for weight-decay (**Res-Adap-WD**) in En→De), at the cost however of a small drop in performance for the other domains. Using layer regularization proves here to be comparatively less effective. Finding better ways to set the regularization parameters, for instance by varying λ for each domain based on the available supervision data, is left for future work.

3.6 Highway and Gated Residual Adaptaters

We now turn to the evaluation of our new architectural variants: Highway residual adapters **Res-Adap-HW** on the one hand, and Gated residual adapters **Res-Adap-Gated** on the other hand. We use the same domains and settings as before, focusing here exclusively on the language direction En→Fr.

To also evaluate the robustness with respect to out-of-domain examples, we perform two additional experiments. We first generate translations with erroneous (more precisely: randomly assigned) domain information: the corresponding results appear in Table 6 under column RND. We also compute translation for a domain unseen in training (NEWS) as follows. For each sentence of this test set, we automatically evaluate the closest domain,[12] then use the predicted domain label to compute the translation. This is an error-prone process, which also challenges the robustness of our multi-domain systems. Results are in Table 6.

A first observation is that for domains seen in training, our variants **Res-Adap-HW** and **Res-Adap-Gated** achieve BLEU scores that are on a par to those of the original version (**Res-Adap**), with insignificant variations across test sets.

The two other settings are instructive in several ways: they first clearly illustrate the brittleness of domain-adapted systems, for which large drops in performance (more than 15 BLEU points on average) are observed when the domain label is randomly chosen. Our gated variant however proves much more robust than the other adaptation strategy and performs almost on par to the generic system for that test condition. The same trend holds for the unseen NEWS domain, with **Res-Adap-Gated** being the best domain adapted system in our set, outperforming the other variants by about 2 BLEU points.

4 Related Work

Training with data from multiple, heterogeneous sources is a common scenario in natural language processing (Dredze and Crammer, 2008; Finkel and Manning, 2009). It is thus no wonder that the design of multi-domain systems has been proposed for many tasks. In this short survey, we exclusively focus on machine translation; it is likely that similar methods (parameter sharing, instance selection/weighting, adversarial training, etc) have also been proposed for other tasks.

Early approaches to multi-domain MT were proposed for statistical MT, either considering multiple data sources (eg. Banerjee et al. (2010); Clark et al. (2012); Sennrich et al. (2013); Huck et al. (2015)) or domains containing several topics (Eidelman et al., 2012; Hasler et al., 2014). Two main strategies emerge: feature-based methods, where domain labels are integrated through supplementary features; and instance-based methods, involving a measure of similarity between train and test domains.

The former approach has also been adapted to NMT: Kobus et al. (2017); Tars and Fishel (2018) use an additional domain feature in an RNN model, in the form of an extra domain-token or of additional domain-features associated with each word. Chen et al. (2016) apply domain control on the *target* side, using a topic vector to describe the

whole document context. Similar ideas are developed in Chu and Dabre (2018); Pham et al. (2019), where domain differences and similarities are enforced through parameter sharing schemes. Parameter-sharing also lies at the core of the work by Jiang et al. (2019), who consider a Transformer model containing both domain-specific and domain-agnostic heads.

Britz et al. (2017) study three general techniques to take domain information into account in training: they rely on either domain classification or domain normalization on the source or target side. A contribution of this study is an adversarial training scheme to normalize representations across domains and make the combination of multiple data sources more effective. Similar techniques (parameter sharing, automatic domain classification/normalization) are at play in Zeng et al. (2018): in this work, the lower layers of the MT use auxiliary classification tasks to disentangle domain-specific from domain-agnostic representations. These representations are first processed separately, then merged to compute the final translation.

Farajian et al. (2017); Li et al. (2018) are two recent representatives of the instance-based approach: for each test sentence, a small adaptation corpus is collected based on similarity measures and used to fine-tune a mix-domain model. As shown in the former work, also adapting the training regime on a per sentence basis is crucial to make these techniques really effective.

Finally, note that a distinct evolution of the residual adapter model of Bapna and Firat (2019) is presented in Sharaf et al. (2020), where meta-learning techniques are used to make fine-tuning more effective in a standard domain-adaptation setting.

5 Conclusion and outlook

In this paper, we have performed an experimental study of the residual adapter architecture in the context of multi-domain adaptation, where the goal is to build one single system that (a) performs well for domain seen in training, ideally as well as full fine-tuning; (b) is also able to robustly handle translations for new, unseen domains. We have shown that this architecture allowed us to quickly adapt a model to a specific domain, delivering BLEU performance than are much better than the generic, mixed domain baseline, and close the gap with the full-finetuning approach, at a modest computational cost. Several new variants have been introduced and evaluated for two language directions: if none that able to clearly surpass the baseline, residual adapter models, they provide directions for improving this model in practical settings: unbalanced data condition, noise in label domains, etc. In our future work, we would like to continue the development of the gated variant, which, it seems to us, provides a flexible and robust tool to address the various challenges of multi-domain machine translation.

Abstract

When translating "*The secretary asked for details.*" to a language with grammatical gender, it might be necessary to determine the gender of the subject "*secretary*". If the sentence does not contain the necessary information, it is not always possible to disambiguate. In such cases, machine translation systems select the most common translation option, which often corresponds to the stereotypical translations, thus potentially exacerbating prejudice and marginalisation of certain groups and people. We argue that the information necessary for an adequate translation can not always be deduced from the sentence being translated or even might depend on external knowledge. Therefore, in this work, we propose to decouple the task of acquiring the necessary information from the task of learning to translate correctly when such information is available. To that end, we present a method for training machine translation systems to use word-level annotations containing information about subject's gender. To prepare training data, we annotate regular source language words with grammatical gender information of the corresponding target language words. Using such data to train machine translation systems reduces their reliance on gender stereotypes when information about the subject's gender is available. Our experiments on five language pairs show that this allows improving accuracy on the WinoMT test set by up to 25.8 percentage points.

1 Introduction

Most modern natural language processing (NLP) systems learn from natural language data. Findings of social sciences and corpus linguistics, however, indicate various forms of bias in the way humans use language (Coates, 1987; Butler, 1990; Fuertes-Olivera, 2007; Rickford, 2016). Thus the resulting NLP resources and systems also suffer from the same socially constructed biases, as well as inaccuracies and incompleteness (Jørgensen et al., 2015; Hovy and Søgaard, 2015; Prates et al., 2019; Vanmassenhove et al., 2019; Bordia and Bowman, 2019; Davidson et al., 2019; Tan and Celis, 2019). Due to the prevalent use of NLP systems, their susceptibility to social biases becomes an increasingly significant concern as NLP systems not only reflect the biases learned but also amplify and perpetuate them further (Hovy and Spruit, 2016; Crawford, 2017; HLEG, 2019).

This work concerns mitigating the manifestations of gender bias in the outputs of neural machine translation (NMT) systems in scenarios where the source language does not encode the information about gender that is required in the target language. An example is the translation of the English sentence "*The secretary asked for details.*" into Latvian. In English, the gender of "*secretary*" is ambiguous. In Latvian, however, there is a choice between the masculine noun "*sekretārs*" and the feminine noun "*sekretāre*". In cases when sentences do not contain the necessary information, NMT systems opt for translations which they have seen in training data most frequently. Acquiring the necessary information, however, might require analysis of the text beyond the level of individual sentences or require incorporation of external knowledge.

Falling back to biases, however, happens not only in the absence of the required information as NMT systems produce stereotyped translations even when clues about the subject's correct gender are present in the sentence (Stanovsky et al., 2019). This is in line with findings by Vanmassenhove et al. (2019) who suggest that NMT systems produce biased outputs not only because of the biases

*First authors with equal contribution.

Proceedings of the 5th Conference on Machine Translation (WMT), pages 629–638
Online, November 19–20, 2020.

present in data but also due to their tendency to exacerbate them.

To provide means for incorporation of external and explicit gender information, we propose a method for training NMT systems to use word-level gender annotations. To prepare training data, we project grammatical gender information of regular target language words onto the corresponding source language words. Albeit in some cases redundant, we expect that the grammatical gender information contains a useful learning signal that helps narrowing down the lexical choice of the correct target translation. As a result, the NMT system learns to rely on these annotations when and where they are available. In particular, in experiments on five language pairs, we show that the methods proposed here can be used in tandem with off-the-shelf co-reference resolution tools to improve accuracy on the WinoMT challenge set (Stanovsky et al., 2019) by up to 25.8 percentage points.

1.1 Related work

Recent recommendations for ethics guidelines for trustworthy AI recommend removing socially constructed biases at the source, the training data, prior to model training (HLEG, 2019). An example of work on debiasing training data is Zhao et al. (2018) where authors identified sentences containing animate nouns and changed their grammatical gender to the opposite. Zmigrod et al. (2019) take it further by ensuring that not only the animate nouns but also the rest of the sentence is reinflected from masculine to feminine (or vice-versa), thus preserving the morpho-syntactic agreement of the whole sentence. The applicability of this line of work is still to be established as reinflecting sentences with co-references or pairs of parallel sentences in NMT pose an additional challenge.

A different take on addressing gender biases in NMT outputs is the work on alternative generation: given a gender-ambiguous source sentence and its translation, provide an alternative translation using the opposite gender. Habash et al. (2019) approach this as a gender classification and reinflection task for target language sentences to address the first person singular cases when translating from English into Arabic. Bau et al. (2018) analyze trained NMT models to identify neurons that control various features, including gender information, that are used to generate the target sentence. In practice, however, such solutions are limited to simple source sentences where only one alternative in the target language is possible.

A complementary approach is addressing gender bias in NMT as a problem of domain mismatch. When translating TED talks, Michel and Neubig (2018) propose to adapt the NMT model for each speaker's attributes, thus also implicitly addressing previously poorly translated first-person singular cases. Saunders and Byrne (2020) describe methods for NMT model adaptation using a hand-crafted gender-balanced dataset and a translation re-scoring scheme based on the adapted models.

The closest line of work to ours is the work on the incorporation of external gender information in the NMT input. Elaraby et al. (2018) and Vanmassenhove et al. (2018) prepend training data sentences with speaker gender information to improve spoken language translation when translating into languages with grammatical gender. Moryossef et al. (2019) undertakes a similar approach at the inference time using phrases (e.g. *"she said:"*) that imply the speaker's gender. The methods proposed in this work differ from the previous work in terms of annotation granularity: we propose to use token level annotations, while the previous work used one annotation per sentence. As our training data annotations are solely based on grammatical gender, preparing them does not require any external gender information. Thus our approach is also simpler in terms of training data preparation compared to the previous work (Elaraby et al., 2018; Vanmassenhove et al., 2018).

Social Impact We propose methods to mitigate the manifestations of gender bias in the outputs of NMT. Specifically, these methods provide explicit means to incorporate information about subjects referential or social gender in NMT, thus reducing gender-based stereotyping when translating into languages which encode for grammatical gender in animate nouns. An example of a use case and a beneficiary group is the translation of occupational nouns into languages which mark gender and people for whom stereotypes of their profession do not align with their gender. While these methods can relieve gender-based representational harms by reducing stereotyped translations, they, unfortunately, provide no means for better representation of non-binary gender identities.

2 Methods

When translating from languages without grammatical gender to languages with grammatical gender,

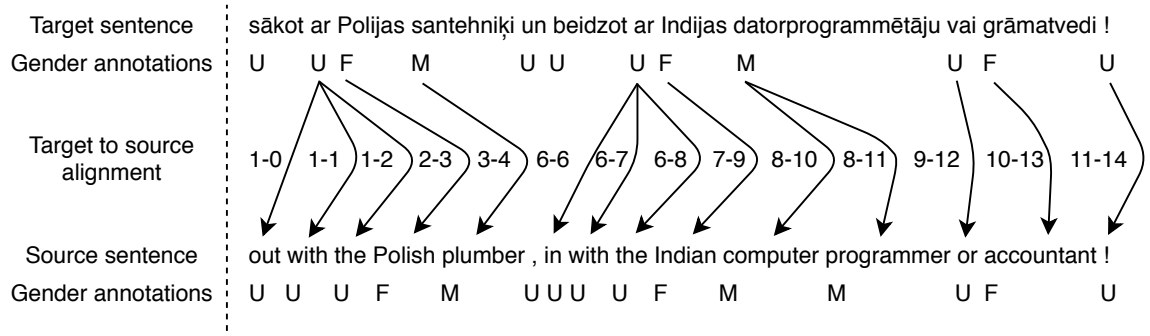

Figure 1: Illustration of target to source projections of grammatical gender annotations. Sample sentences taken from the English-Latvian development set of the WMT2017 News Translation Task.

certain words in the source sentence may not contain all the necessary information to produce an adequate and accurate translation. Examples are pronouns (e.g. *I, me, they, them, themselves*), animate nouns such as job titles and proper nouns such as names and surnames, which depending on the sentence context can be ambiguous and consequently can be translated poorly. Previous work has also shown that NMT systems are better at translating sentences that align with socially constructed gender stereotypes because they are more frequently seen in training data (Stanovsky et al., 2019; Prates et al., 2019).

To circumvent the degradation of NMT outputs due to 1) socially constructed biases and 2) absence of necessary information, we propose a method for training NMT systems to be aware of and use word-level target gender annotations (**TGA**). For training, we use data where regular source language words are annotated with the grammatical gender of their target language translations. We obtain such data by, first, morphologically tagging target language sentences to obtain information about their grammatical gender—`F` for feminine, `M` for masculine, `N` for neuter, and `U` for cases where grammatical gender is unavailable. Then, we use word-level statistical alignments to project this information from the target language to the source language words (see Figure 1 for an illustration). We use source-side factors (Sennrich and Haddow, 2016) to integrate the projected annotations as an additional input stream of the NMT system. To ensure that the NMT systems are capable of producing adequate translations when gender annotations are not available—a frequently expected case at the test time—we apply TGA dropout. We do so by randomly replacing annotations for a random number of words with U.

While useful for animate nouns, such annotations might seem otherwise redundant because the majority of nouns in training data can be expected to be inanimate. However, for some inanimate nouns, the target language grammatical gender annotations can help narrowing down the lexical choice during training. An example is the translation of *"injury"* into Latvian, where "*injury*|`F`" would result in "*trauma*" while "*injury*|`M`" would correspond to "*ievainojums*". Besides disambiguating animate nouns, annotations also disambiguate the grammatical gender of pronouns, proper nouns. Furthermore, grammatical gender annotations also concern adjectives and verbs, which in some languages have to agree in gender with the nouns they describe. Consequently, we expect that during training the NMT model will learn to use these annotations, as they contain valuable information about words in the target sentence.

At inference time, we lean heavily on the observation that there the grammatical gender of animate nouns, pronouns, and proper nouns, and the intended referential gender coincide considerably. This is, however, a heuristic and not a rule (see Hellinger and Motschenbacher (2015) for counterexamples). Nevertheless, we assume that it is possible to use TGA in a referential sense of gender, thus injecting the NMT model with additional information about the subject's gender. Sources of such information can vary; in this paper, we showcase how to use TGA together with off-the-shelf co-reference resolution tools.

2.1 Evaluation: WinoMT Test Suite

To measure the extent to which gender annotations reduce NMT systems' reliance on gender stereotypes, we use the WinoMT test suite (Stanovsky et al., 2019). WinoMT builds on the previous work

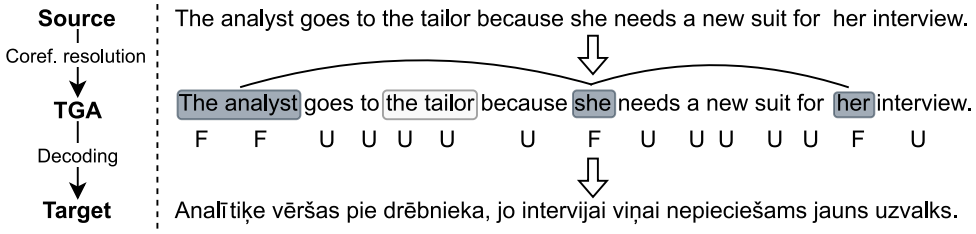

Figure 2: WinoMT test suite translation process with TGA distilled from the output of automatic coreference resolution tool.

on addressing gender bias in co-reference resolution by combining Winogender (Rudinger et al., 2018) and WinoBias (Zhao et al., 2018) datasets in a test suite for automatic evaluation of gender bias in MT. All sentences in the WinoMT test set follow the Winograd Schema where anaphora resolution is required to find an antecedent for an ambiguous pronoun (Hirst, 1981). In the case of datasets designed for evaluation of gender bias, the ambiguous pronoun refers to one of two entities which are referred to using titles of their professions. Professions and pronouns are chosen so that they either align with or diverge from the gender stereotypes of each profession as reported by the U.S. Bureau of Labor Statistics (Zhao et al., 2018).

WinoMT tests if the grammatical gender of the translation of an antecedent matches the gender of the pronoun in the original sentence. Testing is done by morphologically analysing the target translation and aligning it with the source sentence. The WinoMT test suite scores MT outputs using multiple metrics: **Accuracy** – the percentage of correctly translated antecedents, $\boldsymbol{\Delta G}$ – difference in F_1 score between sentences with masculine and feminine antecedents, $\boldsymbol{\Delta S}$ – difference in accuracy between the set of sentences that either align with or diverge from the gender stereotypes of each profession. Saunders and Byrne (2020) also propose to report **M:F** – ratio of translations using masculine and feminine antecedents.

3 Experimental Setting

Languages and Data In all our experiments, we choose one source language without grammatical gender and five Indo-European languages in which nouns have grammatical gender (see Table 1). For all language pairs, we use training data from WMT news translation tasks. We do the necessary cleaning and filtering with Moses (Koehn et al., 2007) pre-processing tools. To see how TGA is affected by data size, we also use much larger EN-LV proprietary data that we obtain from Tilde Data Libarary by combining all EN-LV parallel corpora. The proprietary data are pre-processed using the Tilde MT platform (Pinnis et al., 2018). Table 1 summarizes training data source and size statistics prior to adding TGA. For all systems and language pairs, we use byte pair encoding (BPE) (Gage, 1994; Sennrich et al., 2016) to prepare joint source and target language BPE sub-word vocabularies. We use 30K BPE merge operations and use a vocabulary threshold of 50.

EN-RU	WMT17	25.0M	2015

Table 1: Training data set source and size in millions of sentences prior to adding TGA.

NMT Systems We use the default configuration of the Transformer (Vaswani et al., 2017) NMT model implementation of the Sockeye NMT toolkit (Hieber et al., 2020). The exception is the use of source-side factors (Sennrich and Haddow, 2016) with the dimensionality of 8 for systems using TGA, which changes the model's combined source embedding dimensionality from 512 to 520. We train all models using early stopping with patience of 10 based on their development set perplexity (Prechelt, 1998).

Morphological Taggers The preparation of training data with TGA and WinoMT evaluation relies on the outputs of a morphological tagger. If the tagger produces biased outputs, the TGA annotations might become too noisy to be useful. Furthermore, a biased morphological tagger

Tagger	F1 masc.	F1 fem.
Paikens et al. (2013)	98.6	98.7
Stanza	94.7	95.1
UDPipe	92.5	92.4

Table 2: Performance of morphological taggers on gender feature classification evaluated on the Universal Dependencies test set.

could also render WinoMT evaluation unreliable. Thus we first benchmark several morphological taggers on grammatical gender feature classification. We use Latvian as a development language because of the availability of lexicon-based and data-driven morphological analysis tools. Specifically, we use the Universal Dependencies [1] test set to compare two data-driven tools – the Stanza toolkit (Qi et al., 2020) and UDPipe (Straka and Straková, 2017). Additionally, we evaluate a dictionary-based morphological analyser and statistical tagger[2] by Paikens et al. (2013). Table 2 gives F-1 scores on masculine and feminine feature tagging. Results indicate that none of the taggers exhibits salient bias in their tagging performance. As the only non-neural system yields better F-1 scores than the other two systems, we further compare Stanza and the tagger by Paikens et al. (2013) in their impact on BLEU and WinoMT metrics. Results indicated that the choice of the tagger does not have a notable effect on BLEU scores. In terms of WinoMT accuracy scores, the NMT system that was trained using TGA prepared with Stanza yields an accuracy that is about 3% better than the system using the tagger by Paikens et al. (2013). Thus, in all remaining experiments, we use the Stanza tagger as it provides pre-trained models for a wide range of languages.

TGA in Training Data Preparing training data with TGA requires statistical word alignments between words of source and target language sentences and a target language morphological tagger. To obtain word alignments, we use *fast_align* (Dyer et al., 2013). To obtain grammatical gender information of target language words, we use the Stanza morphological tagger. When training NMT systems with TGA, we combine two copies of the original training data: one where all source-side factors are set to `U` and the other containing TGA.

TGA During Inference In training data, TGA annotate regular source language words with the grammatical gender information of corresponding target language words. We do not have access to the target language sentence during inference. Thus, we use co-reference resolution tools and extract the referential gender information from the source sentence instead. To do so, we first use co-reference resolution tools to obtain the co-reference graph. We then identify sub-graphs which contain gendered pronouns. Finally, we propagate the gender information within the graph and annotate the antecedents (see Figure 2). We set the annotations for the remaining unannotated words to `U`.

We use neural co-reference resolution tools by AllenNLP [3] (Lee et al., 2017) and Hugging Face[4] (based on work by Clark and Manning (2016)). We refer to these systems as **TGA AllenNLP** and **TGA HuggingFace** respectively. We also report the performance of NMT with TGA, when TGA use oracle information directly taken from WinoMT datasets and refer to these as **TGA Oracle**.

Evaluation We evaluate general translation quality using the BLEU (Papineni et al., 2002) metric evaluated over WMT test sets. To calculate BLEU, we use SacreBLEU[5] (Post, 2018) on cased, detokenized data. Reference test sets are only pre-processed using Moses punctuation normalization script[6]. We use the WinoMT test suite (Stanovsky et al., 2019) to measure gender bias of our NMT systems.

4 Results and Discussion

Results from experiments evaluating gender bias using the WinoMT test suite are provided in Table 3. First, we observe that all baseline systems show a strong bias towards generating translations using masculine forms. The EN-RU baseline system is the most biased as it produces only one translation hypothesis with a feminine antecedent for every 8.4 hypotheses containing masculine antecedents. Meanwhile the EN-DE baseline system

Table 3: Results on WinoMT test suite.

is the least biased with the M:F ratio being much lower – 2.6 (see the last column of Table 3). Our baseline systems for EN-DE, EN-FR and EN-RU language pairs, however, show comparable ΔG and WinoMT accuracy results to those reported by Stanovsky et al. (2019) for several publicly available commercial systems. These results confirm that our baselines, although being strongly biased, are not unordinary.

Results from experiments using TGA with oracle gender information show an improvement in WinoMT accuracy and ΔG for all language pairs (see Table 3 TGA Oracle). These results demonstrate that when training MT systems to use TGA reduces their reliance on gender stereotypes when information about the subject's gender is available, proving the usefulness of methods proposed here. Despite the availability of oracle gender information, none of the systems is entirely bias-free or obtains 100% accuracy. Thus methods proposed here could be combined with others, such as those proposed by Saunders and Byrne (2020), to achieve further improvements.

Effect on BLEU As expected, using TGA with reference sentence grammatical gender annotations has a positive effect on BLEU, thus confirming our hypothesis why and how the NMT system learns to rely on TGA as an additional source of information during training (see Table 4). It is equally important, however, that, when training NMT systems to use TGA, it does not degrade their performance when gender information is not necessary or is unavailable. Thus we test our systems for such cases by setting all TGA values to `U` and compare them to the baseline systems (see Table 4). To test for statistically significant differences between the results of NMT systems we use pairwise bootstrap resampling (Koehn, 2004) and significance threshold of 0.05. Results indicate no statistically significant differences between systems using uninformative TGA values and their baseline counterparts with an exception of results for EN-RU systems ($\Delta 0.4$ BLEU), which we find to be statistically significant.

Effect of Data Size To analyze gender bias and TGA performance depending on the quality and size of the training data, we use much larger EN-LV proprietary data (see Table 1) to train production-grade NMT systems and contrast them with EN-LV WMT data systems (see the two EN-LV sections in Table 3 and Table 5). First of all, we notice that although the large data baseline has higher WinoMT accuracy than the WMT data system, it has a similar ΔG. Decomposing ΔG as male and female grammatical gender F-1 scores (Table 5), however, clarifies that, although similarly skewed, the large data baseline has higher F-1 scores than the WMT data baseline. Next, we note, that larger training data size has a positive effect on the system's ability to use TGA more effectively as the large data system using TGA has a greater improvement on the two metrics measuring bias – ΔG and M:F[7] than its WMT data counterpart relative to its baseline. These findings suggest that TGA is a method that is applicable not only in small data settings but also in large data settings, such as commercial systems, for which it is even more effective.

Plugging-in Co-reference Resolution Tools Finally, we experiment with TGA using gender information provided by two off-the-shelf co-reference resolution tools, AllenNLP and Hugging Face. Re-

[7] ΔS results are not reliable or comparable when M:F ratios are large or differ by a large value. See result section of Saunders and Byrne (2020) for more discussion.

sults show that using TGA with either of the tools outperforms baseline systems for all languages pairs. Furthermore, TGA with gender information provided by AllenNLP shows only a 4.5 to 7.1% drop in WinoMT accuracy compared to results when using TGA with oracle information. To put this in perspective, Saunders and Byrne (2020) required a handcrafted gender-balanced profession set and additional rescoring models, for their EN-DE system to obtain comparable WinoMT accuracy and ΔG without loss of translation quality. In contrast, the methods proposed here require tools that are readily available, making them easily applicable in practice.

5 Conclusions

We proposed a method for training MT systems to use word-level annotations containing information about the subject's gender. To prepare training data, the method requires a morphological tagger to annotate regular source language words with grammatical gender information of the corresponding target language words. During inference, annotations can be used to provide information about subjects' referential or social gender obtained by analyzing text beyond sentence boundaries or externally. In experiments with five language pairs, we showed that using such gender annotations reduces NMT systems' reliance on gender stereotypes in principle. We then further showed one way for how these findings can be used in practice by using off-the-shelf co-reference resolution tools.

The method proposed here decouples the task of acquiring the necessary gender information from the task of learning to translate correctly when such information is available. Thus system's ability to use such information can be achieved independently from its availability at training time. This allows for application-specific sources of gender information. Examples are the translation of chat or social media content, where users may choose to indicate their gender or translation of whole documents, where gender information may be obtained using annotations and anaphora resolution. Thus, we believe that the methods proposed here, will provide means to limit the propagation of gender stereotypes by NMT systems when translating into languages with grammatical gender.

The source code to reproduce our results for the publicly available data sets is published on GitHub[8].

Document-aligned Japanese-English Conversation Parallel Corpus

Matīss Rikters, Ryokan Ri, Tong Li and Toshiaki Nakazawa

Abstract

Sentence-level (SL) machine translation (MT) has reached acceptable quality for many high-resourced languages, but not document-level (DL) MT, which is difficult to 1) train with little amount of DL data; and 2) evaluate, as the main methods and data sets focus on SL evaluation. To address the first issue, we present a document-aligned Japanese-English conversation corpus, including balanced, high-quality business conversation data for tuning and testing. As for the second issue, we manually identify the main areas where SL MT fails to produce adequate translations in lack of context. We then create an evaluation set where these phenomena are annotated to alleviate automatic evaluation of DL systems. We train MT models using our corpus to demonstrate how using context leads to improvements.

1 Introduction

The quality of machine translation (MT) for written text and monologue has vastly improved due to the increased amount of available parallel corpora and recent neural network technologies. However, there is much room for improvement in the context of dialogue or conversation translation. One typical case is the translation from a pro-drop language to a non-pro-drop language where correct pronouns must be supplemented according to the context. The omission of the pronouns occurs more frequently in spoken language than written language. Recently, context-aware MT models attract attention from many researchers (Tiedemann and Scherrer, 2017; Voita et al., 2019) to solve this kind of problem, however, there are almost no parallel conversation corpora with context information except the rather noisy Open Subtitles corpus (Tiedemann, 2016).

A document and sentence-aligned conversation parallel corpus should be advantageous to push MT research in this field to the next stage. In this paper, we introduce a newly constructed document-aligned (DA) Japanese-English conversation corpus, which contains three sub-corpora: Business Scene Dialogue (BSD (Rikters et al., 2019)), Japanese translation of AMI Meeting Corpus (AMI (McCowan et al., 2005)) and Japanese translation of OntoNotes 5.0 (ON (Weischedel et al., 2011)). The corpus contains multi-person conversations in various situations: business scenes, meetings under specific themes, broadcast conversations and telephone conversations.

We supplement the original BSD part with additional data, increasing its size by almost three times. We also enrich the corpus with speaker information and other useful meta-data, and separate balanced versions of development and evaluation data sets.

2 Related Work

There are many ready-to-use parallel corpora for training MT systems, but most of them are in written languages such as web crawl, patents (Goto et al., 2011), scientific papers (Nakazawa et al., 2016). Even though some parallel corpora are in spoken language, they are mostly monologues (Cettolo et al., 2012; Di Gangi et al., 2019) or contain a lot of noise (Tiedemann, 2016; Pryzant et al., 2018). Most of the MT evaluation campaigns such as WMT[1], WAT[2] adopt the written language, monologue or noisy dialogue parallel corpora for their translation tasks. Among them, there is only one clean, dialogue parallel corpus (Salesky et al., 2018) adopted by IWSLT[3] in the conversational speech translation task.

JParaCrawl (Morishita et al., 2019) is a recently announced large English-Japanese parallel corpus built by crawling the web and aligning parallel

sentences. Its size is impressive, but it is composed of noisy web-crawled data and has many duplicate sentences. Compared to our corpus, JParaCrawl does not have meta-information and is not DA.

Voita et al. (2019) evaluate what modern MT systems struggle with when translating from English into Russian and construct new development and evaluation sets based on human evaluation. The sets target linguistic phenomena - dexis, ellipsis and lexical cohesion. The authors also provide code for a context-aware NMT toolkit that improves upon translating these phenomena. In contrast, our development/evaluation sets contain complete documents of consecutive sentences, not broken up into only the sentences requiring context.

3 Corpus Description

Our corpus consists of 3 sub-corpora, each of which originates from different sources - BSD, AMI, and ON. BSD was newly constructed, while AMI and ON are translations of the existing English versions of these corpora. Detailed statistics of the sub-corpora are provided in Tables 1 and 2. BSD consists of the scenes mentioned in Table 1, ON has only two different scenes - broadcast conversation and telephone conversation, and all documents from AMI belong to the meeting scene. There is no particular taxonomy associated with these scenes. Word counts for the English side of the sub-corpora are shown in Table 3. We do not include word counts for the Japanese side since it uses very little spaces and the final word count depends on tokenisation.

3.1 Construction Process

Business Scene Dialogue

This sub-corpus was entirely newly created without using any pre-existing resources. We asked professional scenario writers to write monolingual scenarios (documents), and then asked professional translators to translate the documents. This process was done for both En ↔ Ja directions to ensure a wide range of lexicons and expressions from both languages.

In conversations, the utterances are often very short and vague, therefore it is possible that they should be translated differently depending on the situations where the conversations are taking place. For example, the Japanese expression 「すみません」 can be translated into several English expressions, such as "Excuse me", "Thank you." or "I'm sorry.", depending on context. By using scene information, it is possible to discriminate the translations, which is hard to do with only the contextual sentences. Furthermore, it may be possible to connect scene information to multi-modal MT, i.e., estimating the scene from visual information. Language used in meetings and presentations is often more formal than general chatting or phone calls. This is especially prevalent in Japanese, which has three distinct levels of politeness in the spoken language. Knowing the scene may be useful for adjusting politeness and formality.

AMI Meeting Parallel Corpus

The original AMI Meeting Corpus is a multi-modal dataset containing 100 hours of meeting recordings in English. The parallel version was constructed by asking professional translators to translate utterances from the original corpus into Japanese. Since the original corpus consists of speech transcripts, the English sentences contain a lot of short utterances (*e.g., "Yeah", "Okay"*) or fillers (*e.g., "Um"*), and these are translated into Japanese as well. Therefore, the AMI sub-corpus contains many duplicates (see Table 6).

OntoNotes 5.0

The original OntoNotes is comprised of various genres of text (news, telephone speech, weblogs, newsgroups, broadcast, talk shows) in three languages (English, Chinese, and Arabic) with additional annotated information - syntax and predicate argument structure, word sense linked to an ontology and coreference. We extracted the English subsets of broadcast conversation (BC) and telephone conversation (Tele), and had professional translators translate them into Japanese.

Development and Evaluation Sets

We provide balanced development and evaluation splits from only the BSD sub-corpus as it is the least noisy part. The documents in these sets are balanced in terms of scenes and original languages. The complete statistics are shown in Table 4.

3.2 Analysis

We extend the analysis conducted for BSD (Rikters et al., 2019) to AMI and ON by investigating contextual information requirements for EN→JA

	JA→EN		EN→JA	
Scene	**Doc.**	**Sent.**	**Doc.**	**Sent.**
face-to-face	535	16,481	458	14,858
phone call	279	8,720	256	7,770
general chatting	233	7,674	239	7,372
meeting	224	7,647	265	8,952
training	37	1,379	47	1,549
presentation	17	499	53	1,899
sum	1,325	42,400	1,318	42,400

Table 1: Document (Doc.) and sentence (Sent.) statistics for the full BSD corpus. JA→EN represents documents written in Japanese and translated into English. EN→JA represents the opposite documents.

Set (Scene)	Documents	Sentences	PA	WK
AMI	171	110,483	4	0
ON (BC)	27	14,354	5	3
ON (Tele)	46	14,075	6	0

Table 2: Statistics for translated version of AMI and ON corpora and errors detected in EN→JA MT.

MT. We randomly sample 200 and 100 sentence pairs from ON and AMI respectively. In the case of ON, 50% of the pairs are from BC and 50% are from Tele. We translate the sentences with Google Translate[4] and check the translations for errors, ignoring fluency or minor grammatical mistakes. Unlike the JA→EN results for BSD, where more than 50% of errors were due to zero anaphora, there are mainly two types of causes for errors we detected in this analysis - phrase ambiguity (PA) and absence of world knowledge (WK). Most of the errors (Table 2) are caused by PA, for which taking context sentences into account can be considered as a possible solution. On the other hand, the documents in ON-BC contain a variety of named entities (e.g., Shia - one of the two main branches of Islam) and abbreviations (e.g., CPC - Communist Party of China). To solve this, either domain-specific training data or additional mechanisms that take WK into account would be required.

3.3 Release and Licensing

The current version of BSD is published on GitHub[5] under the Creative Commons Attribution-NonCommercial-ShareAlike 4.0 International (CC BY-NC-SA 4.0) license. The English OntoNotes is under the LDC User Agreement for Non-Members and AMI is under Creative Commons Attribution 4.0 license (CC BY 4.0). We plan to release the extended BSD and translations of AMI under the same licenses and are currently negotiating a licensing agreement for the Japanese translations of OntoNotes.

4 Machine Translation Experiments

The conversation corpus alone is not big enough to train real-world NMT systems (as demonstrated by Rikters et al. (2019)). However, by increasing the size of the high-quality BSD corpus, we managed to train reasonable NMT systems. The full statistics of our data are shown in Table 6.

4.1 Experiment Setup

For the SL systems, we used Sockeye (Hieber et al., 2017) to train transformer architecture (Vaswani et al., 2017) models with the *transformer-base* parameters until convergence on development data (no improvement on validation perplexity for 10 checkpoints). Each model was trained 3 times on a single Nvidia TITAN V (12GB) GPU. The reported BLEU score results are an average of 3 runs. Training time was about 2 days for models with only our data and about 5 days when using WMT data.

To train our context-aware systems, we experimented with two approaches - sentence concatenation (Tiedemann and Scherrer, 2017) with source side factors (Sennrich and Haddow, 2016) and context-aware decoder (CADec (Voita et al., 2019)). We use the same toolkit and similar parameters as in our SL systems for the former and the CADec toolkit with the default parameters for the latter. For the concatenation context-aware MT, we experimented with two approaches: 1) prepending the previous sentence from the same document, followed by a beginning of sentence tag <*bos*>, to the source sentence; 2) in addition, providing source side factors to specify if a token represents context or the source sentence.

The source side factors that we used for training were either C or S, representing context and

Table 5: Examples of training data source sentences and the respective source side factors for the concatenated context-aware experiments.

4.2 Results

The results in Table 7 show that decent quality MT models can be trained by using only our corpus. For JA→EN the scores slightly improve by training contextual models (Concatenated and Concatenated + factors), which indicates that there are context-dependent sentences in our evaluation set that benefit from the additional information. We investigate this further by performing human evaluation in Section 5. We did not find a clear reason why models trained with CADec underperformed even our baseline, but one possible explanation could be that it uses three context sentences at once for each sentence and does not overlap them with the previous and next four-sentence lines, which effectively shrinks the training data down to $\frac{1}{4}$th of the original size.

For comparison, we also trained NMT models on WMT20 data (∼13M parallel sentences, excluding *News Commentary v15*; WMT column in Table 7). For these models, we used *newsdev2020* as development data and *News Commentary v15*[6] as evaluation data since *newstest2020* was not yet available at the time and for Japanese *News Commentary v15* was only 1811 sentences long. These models reached 21.14 BLEU for EN→JA and 20.43 BLEU for JA→EN on *News Commentary v15*, but on our evaluation data they under-performed our baselines. This shows that even with 60x the training data these models struggle to translate conversations. By combining all training data the gain over the baselines is only 0.81 - 1.46 BLEU.

Figure 1 shows one example of a Japanese sentence and its translations by the MT systems. There are no pronouns in the source sentence, but there is the noun 「方」, which should be translated into the English pronoun “he”, specifying the person to be the successor to the store. Both systems manage to translate this part correctly, but the baseline generates an additional pronoun in the end instead of “the store”. We observed many similar situations, where the contextual translation still didn’t match the reference and was not perfect, but the selection of pronouns had improved.

5 Human Evaluation

We translated the evaluation set in both directions using our baseline NMT and performed a two step human evaluation similar to Voita et al. (2019). After that, we analysed the remaining sentences to determine which truly require context.

Concatenated	17.07	14.15
Concatenated + factors	17.24	14.19

Table 7: MT experiment results in BLEU scores. WMT uses only WMT 2020 data and WMT+ uses WMT 2020 along with our corpus for training. The rest use only our corpus for training.

We used Yahoo! Japan Crowdsourcing[7] for the human evaluation. Evaluation quality was guaranteed using screening questions which were indistinguishable from the real questions. Only those who correctly answered all the screening questions were considered valid evaluators. Each sentence was evaluated by 5 different evaluators.

In the first step, evaluators were asked to mark each sentence individually as OK or Not Good (NG), where OK meant that the general meaning of the original sentence was transferred to the translation, whereas NG meant that the translation is completely unusable. In the second step, we used only the consecutive pairs of sentences, which were both marked as OK in the first step by at least three evaluators, and asked evaluators to mark them as OK if the corresponding translations made sense in context of each other. We calculated the Free-Marginal Kappa (Randolph, 2005) values for the evaluations to measure agreement between evaluators. The results (overall agreement - 67%, Free-marginal kappa - 0.34) show moderate agreement, which is common for crowdsourcing.

5.1 Analysis

As a result of the crowdsourcing campaign (Table 8) we had 228 EN→JA sentence pairs and 208 JA→EN sentence pairs marked as NG in context of each other. We employed two linguistic experts to check the translations along with their respective sources and references to determine their ambiguity and need for additional context. For this step they were also asked to categorise the ambiguity type.

After the final step 9 EN→JA and 43 JA→EN sentence pairs were marked as context-dependent. 38 JA→EN pairs lack pronouns in the source sentence and do not have enough content to produce an unequivocal translation. The other 5 JA→EN pairs contain ambiguous words or phrases, which can be translated differently, depending on the context. For example, 「1組」 can be translated as either “one couple” or “one group”. Similarly in EN→JA, Chinese can refer to language (中国語) or food (中華料理) as shown in Figure 2. Our best contextual models still struggle to translate such ambiguities, while slightly outperforming SL baselines in handling pronouns.

Figure 3 shows example mistranslations of pronouns, where they are omitted (as is often done in the spoken language) on the Japanese side, but expected in the English translation. The contextual MT model does get some of the pronouns right in the first sentence, but perhaps requires longer context for the second one.

Source: おっ、きっとお店の後継者になる方ですね。
Reference: Oh, he must be the successor to the store.
Baseline: Oh, I’m sure he will succeed **you**.
Con.+fact.: Oh, I’m sure he will be the successor to the store.

Figure 1: JA→EN translations of a sentence where the baseline generated an incorrect pronoun, but the concat. + factors system produced a more fitting translation.

Figure 3: JA→EN MT output by baseline (Base.) and concatenated context + factored (Conc.+f.) models of sentences with no pronouns in the source and expected pronouns in the translation.

evaluation set we marked examples, which can have multiple contrasting translations when tackled on the sentence-level. The release will include the full BSD corpus and Japanese translations of AMI and ON along with instructions on how to align them. The original source language, speaker, scene, document, ambiguity type will also be included.

In the future we plan to model speakers and origin languages in MT, as it can help capture broader context (Maruf et al., 2018) and more precise pronoun translations (Vanmassenhove et al., 2018). We are also interested in experimenting with modelling the scene information within the training data to produce more appropriate translations for each of the politeness settings.

Abstract

We present the results of the 6^{th} round of the WMT task on MT Automatic Post-Editing. The task consists in automatically correcting the output of a "black-box" machine translation system by learning from existing human corrections of different sentences. This year, the challenge consisted of fixing the errors present in English Wikipedia pages translated into German and Chinese by state-of-the-art, not domain-adapted neural MT (NMT) systems unknown to participants. Six teams participated in the English-German task, submitting a total of 11 runs. Two teams participated in the English-Chinese task submitting 2 runs each. Due to *i)* the different source/domain of data compared to the past (Wikipedia vs Information Technology), *ii)* the different quality of the initial translations to be corrected and *iii)* the introduction of a new language pair (English-Chinese), this year's results are not directly comparable with last year's round. However, on both language directions, participants' submissions show considerable improvements over the baseline results. On English-German, the top-ranked system improves over the baseline by -11.35 TER and +16.68 BLEU points, while on English-Chinese the improvements are respectively up to -12.13 TER and +14.57 BLEU points. Overall, coherent gains are also highlighted by the outcomes of human evaluation, which confirms the effectiveness of APE to improve MT quality, especially in the new generic domain selected for this year's round.

1 Introduction

MT Automatic Post-Editing (APE) is the task of automatically correcting errors in a machine-translated text. As pointed out by (Chatterjee et al., 2015), from the application point of view, the task is motivated by its possible uses to:

- Improve MT output by exploiting information unavailable to the decoder, or by performing deeper text analysis that is too expensive at the decoding stage;
- Cope with systematic errors of an MT system whose decoding process is not accessible;
- Provide professional translators with improved MT output quality to reduce (human) post-editing effort;
- Adapt the output of a general-purpose MT system to the lexicon/style requested in a specific application domain.

In its 6^{th} round, the APE shared task organized within the WMT Conference on Machine Translation kept the same overall evaluation setting of the previous five rounds. Specifically, the participating systems had to automatically correct the output of an unknown "black box" (neural) MT system by learning from training data containing human revisions of translations produced by the same system.

This year, the task focused on two language pairs: English-German and English-Chinese. The former has been part of the APE evaluation campaigns since 2016 (Bojar et al., 2016), while the latter represents a new entry. A second difference with respect to previous rounds is that, for both language pairs, the source/domain of the data changed from Information Technology (IT) to Wikipedia articles. The third major novelty factor consists in the type of MT systems used to generate the translations to be corrected. Although for the third year in a row the task focused on translations produced by neural MT (NMT) systems, this year these models were not adapted to the target domain.

These radical changes have advantages and disadvantages. On one side, moving away from the

Proceedings of the 5th Conference on Machine Translation (WMT), pages 646–659
Online, November 19–20, 2020.

"narrow" IT domain allowed to test APE technology on the challenging scenario represented by the generic domain of Wikipedia articles. Indeed, as shown in the previous rounds of the task (Chatterjee et al., 2018a, 2019), the high level of repetitiveness of IT data makes this domain easier to model compared to a generic and less repetitive domain, both for MT and APE technology. Moreover, fixing the output of generic NMT models that are not domain-adapted allowed to test APE on lower-quality initial data and verify its potential as a downstream domain adaptation component. On the other side, the disadvantage of changing domain is the reduced possibility to compare results and measure progress across years. Specifically, the lower quality of the original sentences to be corrected (and, in turn, the larger room for improvement left to APE) make the participants' results and the overall technology advancements difficult to analyze in the light of previous rounds.

Six teams participated in the English-German task, submitting eleven runs in total. Two teams participated in the English-Chinese task, submitting two runs each. Similar to last year, all teams developed their systems based on neural technology, which confirms to be the state-of-the-art approach to APE. In most of the cases (see Section 3), participants experimented with the Transformer architecture (Vaswani et al., 2017), either directly or by adapting it to the task. As in previous rounds, their systems exploit information both from the MT output to be corrected and from the corresponding source sentence. This was done either by concatenating the two, as in last year's winning system (Lopes et al., 2019), or by means of multi-source solutions (Zoph and Knight, 2016) successfully explored in the past (Libovický et al., 2016; Chatterjee et al., 2017). Following the recent trends in other NLP areas, the integration of pre-trained BERT-like language models was also considered. Model ensembling and the integration of word/sentence-level quality estimation techniques geared to APE (similar to (Chatterjee et al., 2018b)) were also explored. Finally, also this year participants took advantage of data augmentation techniques, either by creating their own eSCAPE-like corpora (Negri et al., 2018), or by generating synthetic data by adding artificial noise to simulate post-editing errors, or by exploiting external MT candidates as a source of auxiliary information to be concatenated to the input.

The overall evaluation results show significant improvements over the baseline on both the language directions. On **English-German**, where the "*do-nothing*" baseline (see Section 2.3) was 31.56 TER (Snover et al., 2006) and 50.21 BLEU (Papineni et al., 2002), the top-ranked system (20.21 TER, 66.89 BLEU) shows an impressive -11.35 TER reduction, which corresponds to a +16.68 gain in terms of BLEU score. Considering all the submissions, the average gain is -4.89 TER and +6.5 BLEU points, with only one system performing slightly worse than the baseline. Different from last year, where the differences between the top four submissions were not statistically significant, this year we have a clear winner, whose best submission is 6.78 TER points (and 11.12 BLEU points) above the second ranked team. Nevertheless, though possibly favoured by the relatively low baseline results (+14.72 TER and -24.52 BLEU compared to last year), the globally good performance of the participants is a good indicator of overall progress.

The newly proposed **English-Chinese** task is no exception. Here, both participating teams were able to outperform the baseline (59.49 TER and 23.12 BLEU) by a significant margin. The largest gains are up to -12.13 TER and +14.57 BLEU points and, on average for the four submitted runs, they are -8.15 TER and +10.1 BLEU points.

The good results observed with automatic metrics on both the language pairs are confirmed by the human evaluation outcomes. On English-German, for the first time, the top-ranked primary submission is not significantly worse compared to the human post-edited output (suggesting that automatic corrections are indistinguishable from the human ones[1]). All the other systems except one, moreover, are significantly better than the baseline. This also happens for the two primary submissions to the English-Chinese subtask which, however, are both significantly worse than human post-edits.

All in all, the improvements observed on both the language pairs can be most likely ascribed to the lower quality of the initial translations to be corrected. On English-German, the baseline (31.56 TER, 50.21 BLEU) was indeed much lower

[1]A number of factors (related to this year's data and the overall evaluation setting) may have determined this quite surprising finding. Far from claiming to have reached the "human parity" on the APE task, we leave this aspect to future deeper analyses.

than in the past, when the MT systems used were always domain-adapted and hence more competitive. Last year, for instance, the baseline was 16.84 TER (74.73 BLEU), while in none of the previous rounds focusing on this language pair participants had to confront with TER above 25.0 and BLEU below 62.0. On English-Chinese, the baseline was even lower (59.49 TER, 23.12 BLEU), with the lowest scores across all the past six editions of the APE task. On one side, the large gains observed are in line with (and indirectly confirm) previous observations (Bojar et al., 2017; Chatterjee et al., 2018a, 2019) about the difficulty to improve high-quality MT output. Conversely, as we can observe this year, translations of lower quality (like those coming from generic, not domain-adapted models) leave to APE technology a large margin for improvement. On the other side, the observed global gains in both settings motivate further research on APE as a tool for downstream MT adaptation in black-box conditions.

2 Task description

In continuity with all the previous rounds of the APE task, participants were provided with training and development data consisting of (*source*, *target*, *human post-edit*) triplets, and were asked to return automatic post-edits for a test set of unseen (*source*, *target*) pairs.

2.1 Data

For both English-German and English-Chinese, the initial data were selected from English Wikipedia articles and then automatically translated in the two target languages. Although the original English Wikipedia pages were the same, the source sentences eventually used to build the datasets for the two language pairs are different as they were randomly selected.

The released training and development sets consist of (*source*, *target*, *human post-edit*) triplets in which:

- The source (SRC) is a tokenized English sentence;
- The target (TGT) is a tokenized German/Chinese translation of the source, which was produced by a generic, black-box system unknown to participants. For both the languages, translations were obtained from neural MT systems.[2]
- The human post-edit (PE) is a tokenized manually-revised version of the target, which was produced by professional translators.

Test data consists of (*source*, *target*) pairs having similar characteristics of those in the training set. Human post-edits of the test target instances are left apart to measure system performance.

For the **English-German** subtask, the *training*, *development* and *test* sets respectively contain 7,000, 1,000 and 1,000 triplets. Participants were also provided with two additional training resources, which were widely used in the previous rounds. One is the corpus of 4.5 million artificially-generated post-editing triplets described in (Junczys-Dowmunt and Grundkiewicz, 2016). The other resource is the English-German section of the eSCAPE corpus (Negri et al., 2018). It comprises 14.5 million instances, which were artificially generated both via phrase-based and neural translation (7.25 millions each) of the same source sentences.

Also for the **English-Chinese** subtask, the *training*, *development* and *test* sets respectively contain 7,000, 1,000 and 1,000 triplets. For this language pair, however, no additional training resources were provided.

2.1.1 Complexity indicators: repetition rate

Table 1 provides a view of the data from a task difficulty standpoint. For each dataset released in the six rounds of the APE task, it shows the repetition rate of SRC, TGT and PE elements, the TER (Snover et al., 2006) and the BLEU score (Papineni et al., 2002) of the TGT elements (i.e. the original target translations), as well as the TER difference (δ TER) between the top-ranked submission and the task baseline.

The repetition rate measures the repetitiveness inside a text by looking at the rate of non-singleton n-gram types (n=1...4) and combining them using the geometric mean. Larger values indicate a higher text repetitiveness and, as discussed in (Bojar et al., 2016, 2017; Chatterjee et al., 2018a),

[2]Both the NMT systems are based on the standard Transformer architecture (Vaswani et al., 2017) and follow the implementation details described in (Ott et al., 2018). They were trained on publicly available MT datasets including Paracrawl (Esplà et al., 2019) and Europarl (Koehn, 2005), summing up to 23.7M parallel sentences for English-German and 22.6M for English-Chinese.

Table 1: Basic information about the APE shared task data released since 2015: languages, domain, type of MT technology, repetition rate and initial translation quality (TER/BLEU of TGT). The last row (δ TER) indicates, for each evaluation round, the difference in TER between the baseline (i.e. the "*do-nothing*" system) and the top-ranked submission.

suggest a higher chance of learning from the training set correction patterns that are applicable also to the test set.

Over the years, the relation between systems' performance and the repetition rate observed in the data has been analysed in the light of the different values reported in Table 1. Some rounds of the task suggested the hypothesis that large differences in repetitiveness across the datasets give a possible explanation for the variable gains over the baseline achieved by participants. Indeed, in some cases (e.g. in the APE15 task and in the APE17 German-English subtask), low repetition rates seemed to motivate generally low systems' results, while in others (e.g. APE17 English-German subtask) also the opposite was true, with large gains over the baseline associated to high repetition rates. However, the outcomes of other rounds of the task do not support this intuition. In the 2018 round, despite the relatively high repetition rate values observed in the data, evaluation results shown that the influence of data repetitiveness on final APE performance is marginal. The same happened in 2019 (Chatterjee et al., 2019), when the highest repetition rates ever measured in the APE data (English-Russian subtask) were not enough to develop systems able to improve over the baseline.

As discussed in Section 4, this year we are in the opposite situation. On both English-German and English-Chinese, the lowest repetition rates ever measured in the APE data did not prevent participants from achieving considerable gains over the baseline. This confirms that, as hypothesized last year, systems' improvements over the baseline are either scarcely correlated to text repetitiveness or more influenced by other task difficulty indicators.

2.1.2 Complexity indicators: MT quality

Indeed, another important aspect that determines the difficulty of APE is the initial quality of the MT output to be corrected. This can be measured by computing the TER (↓) and BLEU (↑) scores (Baseline TER/BLEU rows in Table 1) using the human post-edits as reference.

As discussed in (Bojar et al., 2017; Chatterjee et al., 2018a, 2019), numeric evidence of a higher quality of the original translations can indicate a smaller room for improvement for APE systems (having, at the same time, less to learn during training and less to correct at test stage). On one side, indeed, training on good (or near-perfect) automatic translations can drastically reduce the number of learned correction patterns. On the other side, testing on similarly good translations can drastically reduce the number of corrections required and the applicability of the learned patterns, thus making the task more difficult.

As observed in the previous APE evaluation rounds, there is a noticeable correlation between translation quality and systems' performance. In 2016 and 2017, on English-German data featuring a similar level of quality (24.76/24.48 TER, 62.11/62.49 BLEU), the top systems achieved significant improvements over the baseline (-3.24 TER and +5.54 BLEU in 2016, -4.88 TER and +7.58 BLEU in 2017). In 2017, on higher quality German-English data (15.55 TER, 79.54 BLEU), the observed gains were much smaller (-0.26 TER, +0.28 BLEU). In 2018, the correction of English-German translations produced by a phrase-based system (24.24 TER, 62.99 BLEU) yielded much larger gains (up to -6.24 TER and +9.53 BLEU) compared to the correction of higher-quality neural translations (16.84 TER, 74.73 BLEU), which resulted in TER/BLEU variations of less than 1.00 point. Similarly, in 2019 the very high translation

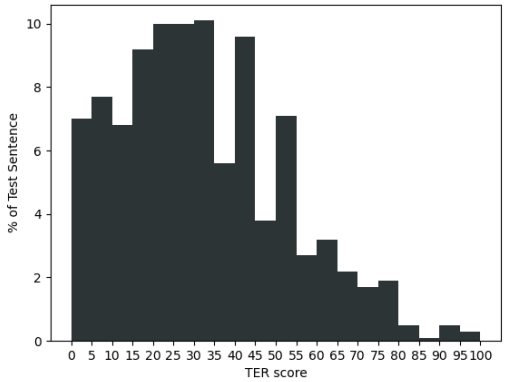

Figure 1: TER distribution in the **English-German** test set

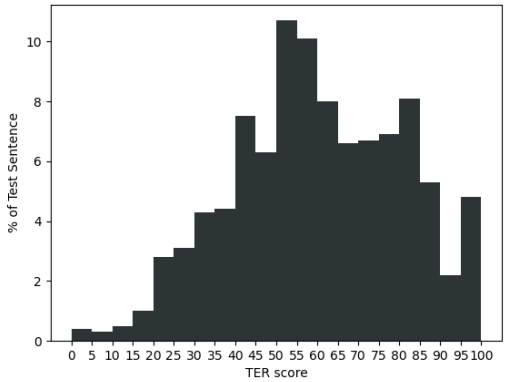

Figure 2: TER distribution in the **English-Chinese** test set

quality featured by strong, domain-adapted neural models made the task rather difficult. On English-German, where the baseline system was again very competitive (16.84 TER, 74.73 BLEU), the largest TER reduction was indeed of 0.78 points (corresponding to a BLEU increase of 1.23). On English-Russian, where the initial MT quality was even higher,[3] (16.16 TER, 76.2 BLEU), the baseline remained unbeaten.

As discussed in Section 4, also this year's results confirm the strict correlation between the quality of the initial translations and the actual potential of APE. Indeed, with baseline TER and BLEU scores significantly lower than in all the other rounds of the task (31.56 TER and 50.21 BLEU for English-German, 59.49 TER and 23.12 BLEU for English-Chinese), almost all participants managed to obtain very large improvements despite the low repetition rates featured by the data.

2.1.3 Complexity indicators: TER distribution

A third complexity indicator considered in previous rounds of the task is the TER distribution (computed against human references) for the translations present in the test sets. What we observed in the past is that harder tasks were typically characterized by TER distributions particularly skewed towards low values. For instance, in 2019 around 50% of the English-German and 63.5% of the English-Russian test items had a TER between 0 and 10, the latter subtask being considerably more difficult than the former (recall that, on English-Russian, none of the participants was able to beat the baseline). Indeed, the higher the proportion of (near-)perfect test instances (i.e. items with $0<\text{TER}<10$, which hence require few edits or no corrections at all), the higher the probability that APE systems will perform unnecessary corrections that will be penalized by automatic evaluation metrics.

On the contrary, less skewed distributions can be expected to be easier to handle as they give to automatic systems a larger room for improvement. In the lack of more focused analyses on this aspect, we can hypothesize that, in ideal conditions from the APE standpoint, the peak of the distribution would be observed for "post-editable" translations containing enough errors that leave some margin for focused corrections, but not too many errors to be so unintelligible to require a whole re-translation from scratch.[4]

As shown in Figures 1 and 2, the TER distributions in the two test sets released this year is quite different from previous rounds and actually reflects a more balanced situation. For English-German, about 55% of the samples falls in the 15-45 TER interval, with no more $\sim 7\%$ of the items being perfect (i.e. TER=0). For English-Chinese, for which the overall MT quality is significantly lower (as shown by the worse baseline results reported in Table 1), the vast majority of the samples falls in the 40-85 interval, with less than 1% of the

[3] Note that the higher quality of the initial translations added up to the higher difficulty of dealing with a morphologically-rich target language like Russian. The two aspects are clearly tightly connected and disentangling them would require further analysis. Nonetheless, regarding the correlation between MT quality and final results, also this subtask was not an exception compared to the other settings summarized in Table 1.

[4] For instance, based on the empirical findings reported in (Turchi et al., 2013, 2014), TER=0.4 is the threshold that, for human post-editors, separates the "post-editable" translations from those that require complete rewriting from scratch.

items being perfect.

In the light of previous years' observations, both the subtasks hence seem to be easier to handle. As discussed in Section 4, also this year's evaluation results confirm the strict correlation between the quality of the initial translations, the distribution of TER scores across the test items, and the actual potential of APE.

2.2 Evaluation metrics

System performance was evaluated both by means of automatic metrics and manually. Automatic metrics were used to compute the distance between *automatic* and *human* post-edits of the machine-translated sentences present in the test sets. To this aim, TER and BLEU (case-sensitive) were respectively used as primary and secondary evaluation metrics. Systems were ranked based on the average TER calculated on the test set by using the TERcom[5] software: lower average TER scores correspond to higher ranks. BLEU was computed using the multi-bleu.perl package[6] available in MOSES. The evaluation results computed in terms of automatic metrics are presented and discussed in Section 4).

Manual evaluation was conducted via source-based direct human assessment (Graham et al., 2013; Cettolo et al., 2017; Bojar et al., 2018). Details are discussed in Section 6.

2.3 Baseline

In continuity with the previous rounds, the official baseline results were the TER and BLEU scores calculated by comparing the raw MT output with human post-edits. In practice, the baseline APE system is a "*do-nothing*" system that leaves all the test targets unmodified. Baseline results, the same shown in Table 1, are also reported in Tables 3 and 4 for comparison with participants' submissions.[7]

For each submitted run, the statistical significance of performance differences with respect to the baseline was calculated with the bootstrap test (Koehn, 2004).

3 Participants

Six teams submitted a total of 11 runs for the English-German subtask. Two of them participated also in the English-Chinese subtask by submitting 2 runs each. Participants are listed in Table 2, and a short description of their systems is provided in the following.

Alibaba Group (*MinD*). Alibaba participated only in the English-German subtask. Their submission introduces a cross-lingual Bert-like conditional model with a "memory-encoder", which can capture the semantic information of machine translations conditional on the source sentences (Fan et al., 2019). The system consists of three parts, namely: *i)* a general Transformer encoder to encode the source sentences, *ii)* a Transformer decoder without future mask adapted to a memory-encoder to encode machine translations with cross attention to the source encoder, and *iii)* a multi-source Transformer decoder to generate the automatic post-editing results with cross attentions to both the encoders. In addition, data augmentation, corpus filtering and imitation learning strategies are exploited to overcome the scarcity of real APE data and to further improve model's performance, together with model ensembling and conservativeness penalty strategies inspired by (Lopes et al., 2019).

[5] http://www.cs.umd.edu/~snover/tercom/

[6] https://github.com/moses-smt/mosesdecoder/blob/master/scripts/generic/multi-bleu.perl

[7] In addition to the *do-nothing* baseline, in the first three rounds of the task we also compared systems' performance with a re-implementation of the phrase-based approach firstly proposed by Simard et al. (2007), which represented the common backbone of APE systems before the spread of neural solutions. As shown in (Bojar et al., 2016, 2017), the steady progress of neural APE technology has made the phrase-based solution not competitive with current methods reducing the importance of having it as an additional term of comparison. Since 2018, we hence opted for considering only one baseline.

Bering Lab (*BerlingLab*). Bering Lab participated only in the English-German subtask. Their system relies on a Transformer architecture, in which the encoder takes in input a concatenation of the source and MT sentences to generate a cross-lingual representation to be passed to the decoder. Additionally, they explored methods to improve APE performance through word-level and sentence-level quality estimation (QE). Based on word-level QE, they mask incorrect or missing words in the PE output. Then, the most probable word for each masked token is predicted using XLM-RoBERTa (Conneau et al., 2020), which is fine-tuned based on the translation language modeling (TLM) objective (Conneau and Lample, 2019). Finally, they propose an output selection mechanism based on sentence-level QE to prevent over-correction. To this aim, they select the sentence with the lowest predicted HTER among the PE outputs and the original MT sentence as the final output. For data augmentation, they use a parallel corpus to train an NMT model and generate artificial triplets, following the ideas from (Negri et al., 2018).

Huawei (*HW-TSC*). Huawei participated both in the English-German and English-Chinese subtasks. Their system basically follows the architecture of last year's winning system (Lopes et al., 2019), where *src* and *mt* sentences are concatenated as input to the encoder, and the decoder is used for decoding the *pe* sentence. However, there are several differences with respect to (Lopes et al., 2019). First, instead of using a pre-trained BERT model, the system relies on a Transformer NMT model (implemented with fairseq (Ott et al., 2019)), pre-trained on the WMT19 news translation corpora. Second, the model integrates bottleneck adapter layers to prevent from over-fitting. Third, external MT candidates (from Google Translate) are exploited as a source of auxiliary information. This results in a longer input sequence composed of (*src*, *mt*, *auxiliary_mt*) triplets. Due to the domain change introduced this year, system's training does not exploit the supplied additional corpora for data augmentation. Finally, the system does not include methods to prevent over-correction, such as the penalty mentioned in (Lopes et al., 2019).

POSTECH (*POSTECH_TERNoise*). This team participated only in the English-German subtask. They mainly focused on increasing the size of the APE data to overcome the scarcity of training samples available. They first introduced a noising module simulating the four types of post-editing errors: insertion, deletion, substitution and shifting. This noising module implants the simulated errors into the target text of the parallel corpora, so to exploit a synthetic MT output during the training phase. The quantity of noise is determined by using the TER distribution of the official training set. They then applied the same generation method proposed in (Negri et al., 2018), so to create a synthetic APE corpus to be used as additional training data. For this data construction process, they used the parallel corpora and the NMT model released for the WMT20 Quality Estimation shared task. As APE model, they chose the sequential model proposed in (Lee et al., 2019), applying some minor modifications to increase the training efficiency. They submitted two ensemble models. Their primary submission (TERNoise-Ops-Ens8) is an ensemble of eight runs. It was obtained by first selecting the top-5 runs having the lowest TER on the development set, for three individual weight initializations. Out of them, they then selected the top-2 runs showing most frequent corrections for each of the four edit operations to form the ensemble. The contrastive submission (TERNoise-nFold-Ens8) is an ensemble of eight runs obtained from models trained/validated in a 4-fold setting on the integration of training data and development data, aiming at the generalization to unseen data. Then, the top-2 runs for each fold were selected to form the ensemble.

POSTECH-ETRI (*POSTECH-ETRI*). This team participated both in the English-German and English-Chinese subtasks. Their models focus on adapting to the APE task XLM (Conneau and Lample, 2019), which can learn joint representations from two languages. Rather than using the open model published on the XLM github page[8] trained on 15 languages, they built new MLM+TLM models that are trained on datasets consisting of only the source and target languages for both language pairs (English-German and English-Chinese). Their model architecture is an extension of Transformer, in which the encoder is initialized with the weights of the pre-trained

XLM, receiving the concatenation of the two input sentences. The decoder is also initialized in a similar manner as the encoder, while multi-head attention layers are random-initialized. At the APE training stage, in addition to the WMT20 official dataset, they generated new synthetic triplets, following the same method used to build eSCAPE (Negri et al., 2018). They used the NMT model provided by the WMT20 quality estimation shared task to generate new synthetic APE triplets by translating the parallel corpus provided by the same task. Finally, to generate their final submissions, they built an ensemble of multiple models.

4 Results

Participants' results are shown in Tables 3 (English-German) and 4 (English-Chinese). The submitted runs are ranked based on the average TER (case-sensitive) computed using human post-edits of the MT segments as reference, which is the APE task primary evaluation metric. The two tables also report the BLEU score computed using human post-edits, which represents our secondary evaluation metric.

Similar to last year, also in this round the primary and secondary evaluation metric produce rankings that are only slightly different from each other.[9] In spite of these minor difference, for both both languages we have a clear separation between the two top-ranked submissions (by the same team) and the other submitted runs.

On **English-German**, the best results (20.21 TER, 66.89 BLEU) respectively outperform the baseline by -11.35 TER and +16.68 BLEU points, the second-best scores being lower by less than 1 point for both the metrics. All the other runs but the last are quite close to each other, being concentrated respectively in a 1.42 TER and 1.55 BLEU points interval.

On **English-Chinese**, the best results (47.36 TER, 37.69 BLEU) respectively outperform the baseline by -12.13 TER and +14.57 BLEU points. Also in this case, the second-best run is below the top-ranked one by less than 1 point for both the metrics, while the third and fourth submissions are close to each other (the difference is less than 0.2 points for both metrics).

All in all, these results indicate that:

- Operating with lower-quality output produced by generic (i.e. not domain-adapted) NMT systems run on a broad "domain" like Wikipedia texts (as opposed to the narrow domains of information technology or medical) leaves considerable room for improvement to state-of-the-art APE models. Looking at the baseline scores and the δTER values shown

[9] For English-German, the third and fourth-ranked submissions in terms of TER are switched in terms of BLEU, as well as the fifth and the sixth. For English-Chinese, this happens for the third and fourth-ranked submissions. The correlation between the ranks obtained by the two metrics is however very high, and in both cases above 0.99.

The "Prec." column shows systems' precision as the ratio between the number of improved sentences and the total number of modified instances.

in Table 1, we can observe that the largest improvements over the baseline were obtained this year on the lowest-quality translations.

- Operating with data featuring low repetition rates does not necessarily prevent from obtaining significant MT quality improvements. Looking at the δTER and the repetition rate values shown in Table 1, we can observe that the lowest data repetitiveness observed this year did not prevent from observing, at the same time, the largest gains over the baseline.

- Operating with data featuring variable quality, with a distribution of the instances that is not too peaked towards high-quality translations, sets ideal conditions for APE. Looking at the δTER and the TER distributions shown in Figures 1 and 2, we can observe that the largest improvements over the baseline achieved this year are also related to a quality distribution that is more uniformly spread around central values of the 0-100 TER interval.

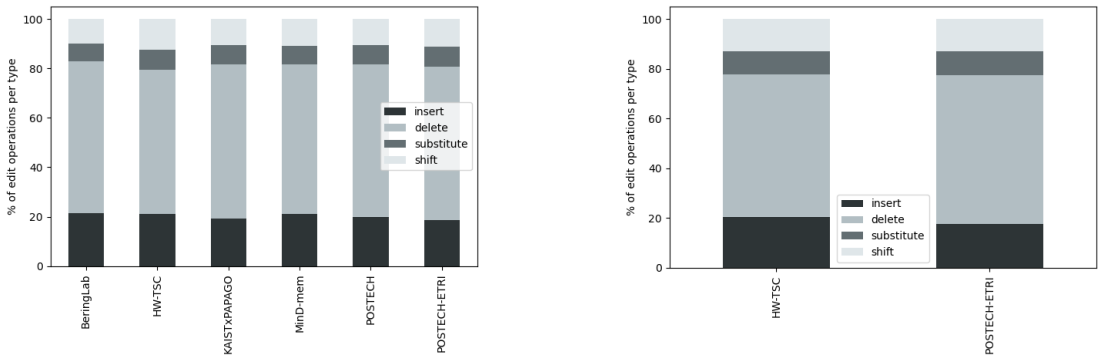
5 System/performance analysis

As a complement to global TER/BLEU scores, also this year we performed a more fine-grained analysis of the changes made by each system to the test instances.

5.1 Macro indicators: modified, improved and deteriorated sentences

Tables 5 and 6 show, for each run submitted to the two subtasks, the number of modified, improved and deteriorated sentences, as well as the overall system's precision (i.e. the proportion of improved sentences out of the total number of modified instances). It's worth noting that, as in the previous rounds and in both the settings, the number of sentences modified by each system is higher than the sum of the improved and the deteriorated ones. This difference is represented by modified sentences for which the corrections do not yield TER variations. This grey area, for which quality improvement/degradation can not be automatically assessed, contributes to motivate the human evaluation discussed in Section 6.

As shown in Table 5, on **English-German** the amount of sentences modified by the participants varies from the very high values of the top two submissions (above 90.0%) to the lower scores of the runs placed below them in the ranking (between 42.1% and 77.8%). However, in all the cases the overall number of modified sentences (69.2% on average) is considerably larger than what we observed in the 2019 round (23.53% on average, ranging from 4.01% to 39.1%). This difference can be ascribed to the different nature of the data that, as previously discussed, this year



(a) (b)

Figure 3: System behaviour (primary submissions) for **English-German** (a) and **English-Chinese** (b) – TER(MT, APE)

featured lower MT quality, combined with a distribution that is less skewed towards low TER values. In particular, while last year about 30.0% of the test instances were to be considered as "perfect", this year the proportion of test instances with 0≤TER≤5 is about 7.0%. In light of this, compared to last year, the participants modified a number of test instances that is much closer to the target percentage of sentences to be modified (about 93.0%, i.e. those having TER>0). As one can expect, besides systems' aggressiveness, final performance highly depends also on their precision in applying corrections. The last column of Table 5 shows systems' precision (Prec.) as the ratio between the number of improved sentences and the total number of modified sentences. As can be seen from the table, the two top-ranked submissions are not only the most aggressive (more than 90% modified sentences) but also the most precise ones (precision above 0.68). Overall, all runs but one have a precision above 0.5, with an average value of 0.58 that is larger than the values observed on the same language (but different evaluation conditions) in 2019 (0.46) and in 2018 (0.34). As a consequence, the percentage of deteriorated sentences out of the total amount of modified test items shows a significant drop with respect to the last two rounds of the task. On average, a quality decrease is observed for 23.6% of the test items (it was 47.85% in 2018 and 35.11% in 2019).

As shown in Table 6, on **English-Chinese** we observe similar trends. The four submitted runs are all characterized by a high percentage of modified sentences (97.97% on average) and a very high precision (0.63 on average). This can be explained by the large room for improvement available to APE on this language pair, due to the low MT baseline (59.49 TER, 23.12 BLEU) and to the small number of "perfect" translations (as shown in Figure 2, less than 0.5% of the test items have a 0≤TER≤5).

5.2 Micro indicators: edit operations

In the previous rounds of the APE task, possible differences in the way systems corrected the test set instances were analyzed by looking at the distribution of the edit operations done by each system (insertions, deletions, substitutions and shifts). Such distribution was obtained by computing the TER between the original MT output and the output of each system taken as reference (only for the primary submissions). This analysis has been performed also this year but it turned out to be scarcely informative, as shown in Figure 3. For both the subtasks, the differences in system's behaviour are indeed barely visible. All the submitted runs are characterized by a large number of deletions (on average, 61.11% for English-German and 58.54% for English-Chinese), followed by the insertions (respectively, 20.17% and 19.01%), the shifts (10.98% and 12.98%) and finally the substitutions (7.74 and 9.48). These distributions differ from what we observed in the past. Especially in the last two rounds of the APE task, the largest proportion of edit operations were indeed substitutions (for English-German neural translations, they were 53.6% in 2019 and 53.5% in 2018). Also this difference can be explained by the lower quality of this year's initial translations. In the previous rounds, the generally high fluency of domain-adapted neural MT systems induced the trained APE models to perform light changes, mainly with isolated word substitutions oriented to improve lexical choice. This year, the change of domain and the use of generic models that were not domain-adapted resulted in more

aggressive structural modifications, where lexical changes represent the minority of edit operations.

6 Human evaluation

In order to complement the automatic evaluation of APE submissions, manual evaluation of the primary systems submitted (seven for English-German, three for English-Chinese) was conducted. In this section, we present the evaluation procedure, as well as the results obtained.

6.1 Evaluation procedure

We evaluated the overall quality of the MT and PE output using source-based direct assessment (Graham et al., 2013; Cettolo et al., 2017; Bojar et al., 2018). We used the same instructions that are used in the News Translation track of WMT2020. We hired 25 professional linguists for English-German and 25 professional linguists for English-Chinese. All involved linguists were either native speaker in German or Chinese.

We acquired only a single rating per sentence as we found that professional linguists were more reliable than crowd workers (Toral, 2020). For adequacy, we asked annotators to assess the semantic similarity between the source and a candidate text, labelled as "source text" and "candidate translation", respectively. The annotation interface implements a slider widget to encode perceived similarity as a value between 0 and 100. Note that the exact value is hidden from the human, and can only be guessed based on the positioning of the slider. Candidates are displayed in random order, so to prevent biased assessments.

For our human evaluation campaign, we also include the human post-edits (test.pe) and the unedited, MT output (test.mt). We expect human post-editing to be of higher quality than the output from APE submissions, which in turn should outperform the unedited MT output. We run human evaluation for all primary submissions, the MT output and the human post-edited output.

6.1.1 English→German

Human evaluation results for English-German are summarized in Table 7. The human post-edited output *test.pe* scores best, while the APE output *HW-TSC_CONCAT.pe* is not significantly worse compared to the human post-edited output. Consequently, and rather surprisingly, human and automatic corrections for this language pair seem to be indistinguishable to our evaluators. This interesting finding can be motivated by a number of reasons (the type/quality/quantity of data, the size of the sample, the number of collected judgements) that suggest to avoid exaggerated claims about a reached human parity. Nonetheless, we take it as indicator of a steady progress of APE research. Interestingly, 5 out of 6 APE submissions perform significantly better than the original MT output *test.mt*, demonstrating that APE can be used to improve machine translation output even for high-resource language settings like English-German, as already shown by Freitag et al. (2019). These findings are different from last year's APE task (Chatterjee et al., 2019) where none of the English-German APE submissions was significantly better than the raw MT output.

	Avg	Avg z
test.pe	83.5	0.298
HW-TSC_CONCAT.pe	82.2	0.260
POSTECH-ETRI_XLM-Top3Ens	77.3	0.031
MinD-mem_enc_dec	76.2	-0.008

	Avg	Avg z
test.pe	86.3	0.363
HW-TSC_CONCAT.pe	77.2	-0.063
POSTECH-ETRI_XLM-Top3Ens	77.0	-0.079
test.mt	74.0	-0.221

Table 8: Results for the WMT20 APE **English-Chinese – human evaluation**. Systems ordered by DA score z-score; systems within a cluster are considered tied; lines indicate clusters according to Wilcoxon rank-sum test $p < 0.05$.

6.1.2 English→Chinese

Human evaluation results for English-Chinese are summarized in Table 8. In this case, the human post-edited output does perform significantly better than the two primary submissions. Similar to the English-German task, both APE submissions perform significantly better than the original MT output *test.mt*. Nevertheless, both submissions

perform very similarly, and both submissions can be seen as similar quality.

7 Conclusion

We presented the results from the 6^{th} shared task on Automatic Post-Editing at WMT. This year, we proposed two subtasks in which the MT output to be corrected was respectively generated by English-German and English-Chinese neural systems unknown to the participants. The latter language pair represents a new entry for the task, which previously focused on Spanish (in 2015), German (since 2016) and Russian (in 2019) as target languages. The other major novelty factors are that: *i)* both the subtasks dealt with data drawn from the "generic" domain of Wikipedia articles, and *ii)* the NMT systems used to generate the translations were not domain-adapted. As a consequence, participants had to confront with lower quality translations that left to APE large room for improvement.

Six teams participated in the English-German task, with a total of 11 submitted runs, while two teams participated in the English-Chinese task submitting two runs each. Their results computed with automatic metrics (TER and BLEU) revealed significant gains over the "*do-nothing*" baseline. On English-German, the top-ranked system improved over the baseline by -11.35 TER and +16.68 BLEU points, and the average improvements were the largest ones observed over the years (-4.89 TER, +6.5 BLEU). On English-Chinese the improvements of the top-ranked system are respectively -12.13 TER and +14.57 BLEU points, with average gains of (-8.15 TER and +10.1 BLEU). Our human evaluation confirmed that on both the language pairs, almost all the primary submissions are significantly better than the baseline. On English-German, the improvement is up to the point that the quality of the automatic corrections produced by the top-ranked primary submissions is substantially on par with human corrections.

All in all, these results confirm the effectiveness of APE to improve MT output in black-box conditions, especially when the adaptation of generic systems to a new "domain" is required.

Acknowledgments

We would like to thank Apple and Google Research for their support and sponsorship in organizing the 2020 APE shared task.

Abstract

Machine translation of scientific abstracts and terminologies has the potential to support health professionals and biomedical researchers in some of their activities. In the fifth edition of the WMT Biomedical Task, we addressed a total of eight language pairs. Five language pairs were previously addressed in past editions of the shared task, namely, English/German, English/French, English/Spanish, English/Portuguese, and English/Chinese. Three additional languages pairs were also introduced this year: English/Russian, English/Italian, and English/Basque. The task addressed the evaluation of both scientific abstracts (all language pairs) and terminologies (English/Basque only). We received submissions from a total of 20 teams. For recurring language pairs, we observed an improvement in the translations in terms of automatic scores and qualitative evaluations, compared to previous years.

[*] The author list is alphabetical and does not reflect the respective author contributions.

1 Introduction

Automatic translation aims to alleviate the language barrier by providing access to information for readers not familiar with the original language used to write documents. Access to accurate biomedical information is specifically critical and machine translation (MT) can contribute to making health information available to health professionals and the general public in their own language. It can also contribute to biomedical research by assisting with the writing of research reports in English. In addition, machine translation can provide the opportunity to enhance the use of natural language processing (NLP) tools and methods for low-resource languages by the development of resources through translation or by making tools available through text translation into resource rich languages.

Herein, we describe the fifth edition of the WMT Biomedical task,[1] which aims to evaluate the auto-

Proceedings of the 5th Conference on Machine Translation (WMT), pages 660–687
Online, November 19–20, 2020.

matic translation of a variety of biomedical texts.

The first edition of the task (Bojar et al., 2016) focused on biomedical scientific abstracts in three language pairs. The second edition of the task offered ten language pairs and addressed scientific abstracts as well as patient-oriented health information (Jimeno Yepes et al., 2017). The third edition of the task offered six language pairs and addressed scientific abstracts (Neves et al., 2018). The fourth edition of the task offered ten language pairs. It addressed scientific abstracts and introduced the task of terminology translation (Bawden et al., 2019). This year's edition of the task continues to address the translation of scientific abstracts and terminologies. It builds on previous tasks by offering a large range of training and test sets to support participants' systems. The following language pairs are addressed this year:

- English to Basque (en2eu)
- English to Chinese (en2zh) and Chinese to English (zh2en)
- English to French (en2fr) and French to English (fr2en)
- English to German (en2de) and German to English (en2de)
- English to Italian (en2it) and Italian to English (it2en)
- English to Portuguese (en2pt) and Portuguese to English (pt2en)
- English to Russian (en2ru) and Russian to English (ru2en)
- English to Spanish (en2es) and Spanish to English (es2en)

Similar to previous years, our test sets consist of scientific abstracts retrieved from the MEDLINE® database. In continuation with last year's task (Bawden et al., 2019), we also provide a test set for the automatic translation of biomedical terminologies. Below, we highlight some new aspects introduced in the 2020 edition of the shared task:

- We address three new language pairs, namely, en/eu, en/it, en/ru[2].
- We include a novel test set for the automatic translation of biomedical terminologies from English to Basque (cf. Section 2.2.1)
- During the construction of the test sets, and after the manual validation of the automatic alignment, we ran a pilot project for a couple of languages in which we manually fine-tuned the alignment of the test sets (cf. Section 2.2.3).
- We ran a second pilot study in which we split the sentences according to the reported original language of the abstract (cf. 2.2.3).
- Three of our tests sets, namely, de/en, ru/en and zh/en, were included as test suites in the WMT News Task (cf. Section 5.2).
- Participants were asked to provide details about their systems through an online survey (cf. Tables 6, 7, and 9).
- Our manual validation included whole abstracts, in addition to (correctly aligned) sentence pairs (cf. Section 6.1).
- We ran a third pilot study in which two experts validated submissions for certain language pairs, in which one was a native speaker of the source language, while the other a native speaker of the target language (cf. Tables 17 and Table 20).
- Our methodology for ranking the systems based on the manual validation considered a significance test and a points-based schema (cf. Section 6.1).

This article is structured as follows: Section 2 presents the details of the generation of our training and test sets, for both the scientific abstracts and the terminology, as well as manual validation of the quality of the test sets. Section 3 describes our baseline systems, which are used as comparison in the automatic evaluation. We list all teams that participated in our task in Section 4, as well as details of the methods behind their systems and the in-domain and out-of-domain data that was used. The results of the automatic evaluation based on the BLEU and chrF scores are presented in Section 5, while the ones for the manual evaluation are presented in Section 6. Finally, we discuss various topics related to the shared task in Section 7.

biomedical-translation-task.html

[2]Throughout the paper, we will refer to en/ru (or ru/en), for instance, when referring to the language pair in general, without specifying the translation direction. When making reference to the direction, we will use either en2ru or ru2en, for instance.

2 Training and test data

We provided training data of MEDLINE abstracts for it/en and ru/en, since training data for some of the other languages was already available from previous years. As for the tests sets, we released test sets for scientific abstracts and for terminologies, as summarized below:

- Scientific abstracts:
  - English to Basque
  - Chinese/English (both directions)
  - French/English (both directions)
  - German/English (both directions)
  - Italian/English (both directions)
  - Portuguese/English (both directions)
  - Spanish/English (both directions)
- Terms from biomedical terminologies:
  - English to Basque

Additional details are presented in Table 1. In this section we describe the details about the construction of resources that we released for the shared task.

2.1 Training data

We released training data from MEDLINE for two of the new language pairs that we address this year, namely, English/Italian and English/Russian.

We relied on the latest version of the MEDLINE baseline[3] available at the time of data preparation. We retrieved all the abstracts that were available in Italian and English, or in Russian and English. We summarize below the steps that we followed to process the data:

1. Abstracts were parsed using the `pubmed_parser` library.[4]
2. The language of these abstracts, as identified by MEDLINE meta-data, was confirmed with the `langdetect` library.[5]
3. Sentences in the abstracts were split using the `syntok` library.[6]
4. These sentences were automatically aligned using the `GMA` tool[7] using specific stopword lists for each language.

We obtained a total of 1,675 parallel documents for it/en and 6,029 for ru/en. The training data is available in our GitHub repository.[8]

In regard to English-Basque scientific abstract translation, we could not release any in-domain parallel data, as very little is still written in Basque in the medical domain. However, we provided other corpora that can help with training machine translation models. These include out-of-domain parallel corpora such as the TED talks,[9] the datasets available on the OPUS repository[10] and the WMT16 IT translation shared-task.[11] Additionally, we released in-domain monolingual corpora[12] that include translations of examples of hospital notes, automatic translations of SNOMED CT terms (Perez-de Viñaspre and Oronoz, 2015), and medical domain articles from Wikipedia. Finally, we released a recent dump of the whole Wikipedia (01/2020) as a large, out-of-domain monolingual corpus.[13]

For the terminology translation task, on behalf of Osakidetza (Basque Public Health System), we released 27,900 terms of the Basque ICD-10-CM. These descriptions were manually validated by the institution's translation team. 25,900 descriptions where released as a training set, keeping the remaining 2,000 for the development set. Both sets are plain text, and they have not been tokenized. On average, in the training set, each term comprises 6.72 words (split on whitespace and punctuation), 1 being the minimum and 27 the maximum. For the development set, the average word count is 6.75, 1 being the minimum and 25 the maximum.

2.2 Test sets

All test sets were released on June 29th, 2020 and the participants could submit results until July 9th, 2020. The test sets for de/en, ru/en and zh/en were

Table 1: Number of documents, sentences and terms in the training and test sets released for this shared task.

also included as test suites of the WMT news task and released on June 22nd, 2020. In the following we describe details of the test set construction.

2.2.1 Terminology

In addition to the training set of ICD-10-CM Basque terms, there were 2,000 more terms for the test set. Again, this set was not tokenized. On average, each term comprises 7.74 words, 1 being the minimum word count and 25 the maximum. Unfortunately, at the time of releasing the test set, due to a confusion on behalf of the organizers, the development set was provided as test for all participants, and was used for evaluation. The planned test set has been publicly released for download.[14]

2.2.2 Basque abstracts

The Basque language appears in MEDLINE as a subject of study but not systematically as a writing language, so there is not a sufficient corpus for training in Basque in MEDLINE. The abstracts used in the test are taken from the journal Osagaiz,[15] the first journal on medicine written entirely in Basque (with abstracts also in English).

Osagaiz[16] was published for the first time in 2017 and every year it publishes a volume with at least two numbers. Its main objective is to be a way of communicating the scientific findings of the Basque health community in Basque. Three volumes have been used in the test (years 2017, 2018 and 2019); that is, 6 numbers with 40 abstracts in both English and Basque. The Basque abstracts dataset consists of 375 sentences (8,651 tokens in English with 23.07 tokens per sentence, and 7459 tokens in Basque with 19.89 tokens per sentence).

2.2.3 MEDLINE abstracts

We followed a similar approach to the one we used in previous years. However, we carried out two novel pilot studies this year: (a) a manual improvement of the alignment after the manual validation, and (b) a selective split of the abstracts for the translation directions based on the original language of the abstract.

For the test sets, we retrieved the citations that were published in 2020 and were not included in any of the previously released training and test sets. We parsed the articles and checked the language using the same tools as described for the training data above. We split the sentences for all languages using the `syntok` library, except for zh/en where it was sufficient to split sentences according to the Chinese punctuation (。) that marks the end of a sentence. Sentence alignment was carried out for all languages (except for zh/en) with the `GMA` tool using specific stopword lists for each language. For zh/en, we used the `Champollion` tool[17] with the same configurations and stopword lists since 2018.

[14] https://drive.google.com/drive/folders/1KXUjEBUzudi81y5rxm33UxkmRY9RSKMj

[17] http://champollion.sourceforge.net/

We randomly retrieved a set of 100 abstracts for each language pair, and the automatic aligned sentences were manually validated by native speakers of the foreign languages using the Appraise tool (Federmann, 2010). Results of the validation are shown in Table 2. For the ru/en set, an additional set of 100 abstracts were randomly retrieved for a second round of manual validation. This was due to the low quality of the alignments that we obtained in the first round of validation. The official test set for ru/en was composed of the abstracts with better quality from the totality of 200 abstracts that were validated.

As a pilot study this year, we performed a manual correction of the alignment which were identified as not being correct during the validation in the Appraise tool. This step was only carried our for the es/en, fr/en, ru/en, and zh/en test sets. For all these languages, this extra step increased alignment quality (cf. Table 2): from 80.54% correctly aligned sentences to 91.49% for fr/en, from 55.27% to 61.96% for ru/en, from 83.57% to 88.07% for es/en, and a slight improvement from 63.84% to 64.43% for zh/en.

Most of the remaining sentences are in fact titles in English, for which a translation in the foreign language is not available from MEDLINE. For zh/en, the manual corrections addressed mismatching sentence splitting policies for abstract subsections such as *OBJECTIVE: To investigate...* and *METHODS: We used xyz...* The GMA tool split such a text into two sentences, but the Champollion tool kept it as one sentence. With this extra step, affected sentences that were marked as "NO_ALIGNMENT" became "TARGET_GREATER_SOURCE" (cf. Table 2 for the alignment categories).

Finally, the set of 100 abstracts was randomly split into two sets of 50 abstracts, for each translation direction, e.g., es2en and en2es. Exception was made for the fr/en test set. Following the recommendations of Graham et al. (2019), we tried to split the data sets depending on which language we hypothesized was the abstract's source language. For articles with a documented "TT" field (vernacular, i.e. French, title) in the MEDLINE citation, we considered that the source language was French and otherwise, English. As a result, the en/fr test only contains abstract originally written in English. However, since only 20 abstract in our set were originally written in French, the fr/en set still contains a mix of source languages. This suggests that vernacular titles should be considered in the initial set selection.

3 Baselines

We provided our baseline systems for all language pairs in the scientific abstracts translation subtask.

There were two categories of baseline: for en/zh, en/fr, en/de, en/pt and en/es the models used for each direction were transformers (Vaswani et al., 2017) trained by us using MarianNMT (Junczys-Dowmunt et al., 2018) with the following settings: joint BPE of 40,000, beam size 16. These parameters were chosen by tuning on a single direction of a single language pair: English to German. Each of the 10 models were trained for up to two days. The training was stopped when there were no improvements on the validation dataset for more than 10 epochs, as measured through cross-validation score. The corpora we used to train the models were the same as last year – when we had baselines generated using RNN-based sequence2sequence models: the UFAL medical corpus (UFA) without the "Subtitles" subset, and as validation we again used Khreshmoi (Dušek et al., 2017).

For en/it and en/ru and en/eu we used the Helsinki-NLP/opus-mt-SRC-TRG models (Tiedemann and Thottingal, 2020) included in the huggingface transformers library [18], trained with MarianNMT on the entirety of the OPUS corpora (Tiedemann, 2012). These models are not uniformly good; they performed very well for Italian, but fairly poor for Russian and Basque.

Discussion. It is interesting that the models for English to/from Italian performed so well in the biomedical task, as they were trained on generic text, not targeting the biomedical domain. It is interesting in general to what extent models that excel on generic text (e.g. news) perform well on the biomedical texts as well.

4 Teams and systems

This year, 22 teams submitted a total of 151 runs. Two teams withdrew after submitting their runs. The remaining teams were from China (7 teams), Spain (3 teams), France (2 teams), the United Kingdom (2 teams), Armenia (1 team), Australia (1 team), Brazil (1 team), India (1 team), Ireland (1 team) and Pakistan (1 team). Table 3 presents the

fr/en	985 (80.54%)	34 (2.78%)	74 (6.05%)	6 (0.49%)	124 (10.14%)	1,223
fr/en §	1225 (91.49%)	7 (0.52%)	8 (0.60%)	2 (0.15%)	97 (7.24%)	1,339
it/en	636 (60.40%)	51 (4.84%)	150 (14.25%)	60 (5.70%)	156 (14.81%)	1,053
pt/en	799 (78.41%)	37 (3.63%)	66 (6.48%)	20 (1.96%)	97 (9.52%)	1,019
ru/en *	947 (53.14%)	67 (3.76%)	186 (10.44%)	65 (3.65%)	517 (29.01%)	1,782
ru/en **	472 (55.27%)	33 (3.86%)	94 (11.01%)	32 (3.75%)	223 (26.11%)	854
ru/en §	562 (61.96%)	30 (3.3%)	60 (6.61%)	28 (3.09%)	228 (25.14%)	908
zh/en	535 (63.84%)	36 (4.30%)	135 (16.11%)	9 (1.07%)	123 (14.68%)	838
zh/en §	540 (64.43%)	137 (16.35%)	142 (16.95%)	9 (1.07%)	10 (1.19%)	838

Table 2: Statistics (number of sentences and percentages) of the quality of the automatic alignment for the MEDLINE test sets. For each language pair, the total number of sentences corresponds to the 100 documents that constitute the two test sets (one for each language direction). * Results for the totality (200 abstracts) for ru/en. ** Results for the selected test set (100 abstracts) for ru/en. § Results after manual correction of sentence segmentation and/or alignment.

list of teams that submitted at least one run to the biomedical task.

At least one run was submitted for each language pair offered, with the most runs submitted for English to Basque (terminology test set, 24 runs) and English to Chinese (MEDLINE test set, 18 runs). Table 4 presents an overview of the runs submitted by each team for language directions translating *from* English. Table 5 presents an overview of the runs submitted by each team for language directions translating *into* English.

During the automatic evaluation, we observed that some teams obtained extremely high BLEU scores, which were close to 0.9. Those teams had trained their systems on the MEDLINE database, and the training data potentially included our test sets. Unfortunately, as opposed to previous years, we forgot to inform participants on our website that this practice was not allowed. Therefore, we offered the opportunity for these teams to re-submit their runs, but without training on MEDLINE. The Wei-Bot team was the only one to submit new runs.

In an effort to increase the level of detail in the system description and the comparability between systems, we asked participants to fill in a survey with key information regarding the translation method used, as well as the in-domain and general datasets used for training. The survey comprised 14 questions covering the translation methods and corpora used. Teams indicated their primary submission, which was considered for manual evaluation. On average, submission time for one language pair was 6 minutes and 28 seconds (Median: 3 minutes and 35 seconds). All teams used transformer-based neural machine translation (except for team TRAMECAT, who used sequence2sequence) and mostly relied on existing implementations: 19 teams submitted runs using available libraries, one team submitted runs using a mix of libraries and in-house implementations, one team submitted runs exclusively relying on their own implementation of NMT. Teams often used the same setup for a range of language pairs. Table 6 shows details about the teams methods.

For in-domain data, teams used the training data distributed by us and many of the sources described in (Névéol et al., 2018). Tables 7 and 8 provide details of the in-domain data used by the teams.

For relevant language pairs, parallel data from other WMT tracks (e.g., News Task) was used. Interestingly, some teams used similarity measures based on biomedical corpora to extract additional biomedical sentences from out-of-domain corpora. Out-of-domain data was also used in the form of pre-trained base models. Table 9 shows details of the out-of-domain data used by the teams.

5 Automatic evaluation

Following (Mathur et al., 2020), we used chrF (Popović, 2015) as well as BLEU (Papineni et al., 2002) as automatic metrics. chrF scores are obtained using the `nltk` implementation.[19]

5.1 MEDLINE

Similarly to previous years, we compared the submitted translations to the reference translations

Table 4: Overview of the submissions from all teams and test sets translating from English. We identify submissions to the abstracts testsets with an "A" and to the terminology test set with a "T". The value next to the letter indicates the number of runs for the corresponding test set, language pair, and team.

using BLEU with the `MULTI-EVAL v14` tool[20] provided by the Moses package (Koehn et al., 2007). This means as well that we reused the tokenization approach used for Chinese. Results for MEDLINE BLEU are shown in Tables 10 and 11.

[20] https://github.com/moses-smt/mosesdecoder/blob/master/scripts/generic/mteval-v14.pl

5.2 News

The test set of our challenge was included in the News challenge data set. We identified the translations in the News files and used the same evaluation procedure as applied to MEDLINE abstracts. Results of the systems are shown in Tables 12 and 13.

5.3 Basque abstracts

For the Basque abstract we used the same evaluation tool as for MEDLINE (MULTI-EVAL), and the results are presented in Table 14.

5.4 Terminology

For the evaluation of terminology we provide two metrics for the en2eu task: (i) accuracy, by relying on strict matches (case-insensitive) between ground truth and predictions; and (ii) sentence-level BLEU score, as measured by the `nltk` module sentence-BLEU.[21] Results are presented in Table 15.

6 Manual evaluation

We manually validated a sample for each primary run in order to compare the performance between teams as well as to the reference translations. In this section we present details of the evaluation and results that we obtained.

6.1 MEDLINE abstracts

Similarly to previous years, we aimed to validate a total of 100 sampled sentences per primary run. This year, we manually validated not only single sentences, but also whole abstracts. The selection of abstracts to be validated for each language pair followed the procedure described below:

1. Randomly select an abstract.
2. Check whether the percentage of perfectly aligned sentences is at least of 80%.
3. Retrieve all perfectly (i.e., OK) aligned sentences from the abstract.
4. Repeat steps 1 to 3 above if the total number of selected sentences (over all selected abstracts) is below 100.

In the case of zh2en and en2zh, due to the large number of submissions that we received, the manual validation was restricted to the abstracts. However, these were selected using the same approach described above. In addition, one team re-submitted their results after the official test period, and we note that these re-submissions are not fully comparable to the ones submitted before the period (see Tables 10, 11 and 22).

Due to time constraints, we could not validate all planned abstracts and sentences that were selected for de2en, but only about half of them. Further, and due to the same reason, the validation for es2en and pt2en was limited to a few abstracts (and its sentences) and was validated as a collaboration between two experts: (1) one who was a native speaker of the source language and who checked whether any information that was included in the source text was missing in the translation; and (2) one who was a native speaker of English, and who was in charge of checking the quality of the English translations.

If the information about the primary run was not available for a particular team and test set, we considered the run with the highest BLEU score. We only considered for manual validation those teams that provided detailed information about their system by filling out a survey mentioned in Section 4. The runs that we considered are listed below:

- en2de (5 teams): Huawei United (run3), NLE (run3), TMT (run1), UNICAM (run3), YerevaNN (run3)
- en2es (5 teams): Elhuyar (run1), Ixamed (run1), Sheffield (run1), TRAMECAT (run1), UNICAM (run3)
- en2fr (5 teams): Huawei United (run2), LIMSI (run1), Sheffield (run1), TRAMECAT (run1), nrpu-fjwu (run1)

Table 13: BLEU scores for news test “OK” sentences

tors were native speakers of the target language and had good knowledge of the source language. Each validator was presented with the source sentence (or abstract), and two candidate translations, either from two teams or from one team and the reference translation. The goal of the validator was to decide whether one translation was better than the other or whether they were of similar quality. Sentences could be skipped if the translations seemed to refer to different source sentences. Results for the manual validation are presented in various tables as summarized below:

- en2de and de2en: Table 16
- en2es and es2en: Table 17

Teams	Runs	BLEU

Table 15: Results for the terminology test set (en2eu). * indicates the primary run as indicated by the participants.

- en2fr and fr2en: Table 18
- en2it and it2en: Table 19
- en2pt and pt2en: Table 20
- en2ru and ru2en: Table 21
- en2zh and zh2en: Table 22

We identified the item of each pairwise comparison (if any) that performed better (cf. respective tables) and ran a Wilcoxon Signed-Rank Test using the Python `scipy` library (Virtanen et al., 2020). We consider all comparisons for two particular items over all validated segments (abstracts and sentences), except for skipped segments. The test was calculated for the abstracts and the sentences and we mark in bold in the respective tables if any of them was found to be significant, (p-value< 0.05), otherwise, the two items were considered to be similar. For the language pairs validated by two experts (i.e., es2en and pt2en), we only consider one item of the pairwise comparison to be superior to the other when at least two of the four comparisons (2x for the abstracts, 2x for the sentences) were statistically significant.

To rank the systems, we assign points to each item: 3 points if superior to the opponent, 1 point when they are similar and no points if inferior to the opponent. Based on this methodology, we ranked the systems and the reference translations as summarized below (the obtained points are shown in parentheses):

- en2de: UNICAM (1) < reference (5) < YerevaNN (6) < Huawei-United (7) = NLE (7) < TMT (9)
- en2es: reference (2) < TRAMECAT (4) < Sheffield (5) < Ixamed (6) = UNICAM (6) < Elhuyar_NLP (11)
- en2fr: Sheffield (2) < TRAMECAT (3) = LIMSI (3) < nrpu-fjwu (5) < Huawei United (12) < reference (15)
- en2it: Sheffield (0) < reference (4) = Huawei United (4)
- en2pt: UNICAMP_DL (0) < reference (3) = Sheffield (3)
- en2ru: Sheffield (1) < TRAMECAT (2) < Huawei United (4) < YerevaNN (9) < reference (12)
- en2zh: TRAMECAT (1) < TMT (6) < baidu (10), ai_not_intellegent (10) < Wei-Bot (12) = OOM (12) = Huawei United (12) = Alibuba (12) = reference (12)
- de2en: UNICAM (2) < TMT (5) = reference (5) < Huawei United (7) = YerevaNN (7) = NLE (7)
- es2en: reference (5) = Ixamed (5) = NLE (5) = Sheffield (5) = TRAMECAT (5) = UNICAM (5)
- fr2en: npru-fjwu (0) < TRAMECAT (4) = Sheffield (4) < reference (11) = NLE (11) = Huawei United (11)
- it2en: Sheffield (0) < reference (4) < NLE (5) < Huawei United (7)

- pt2en: reference (2) = UNICAMP_DL (2) = Sheffield (2)
- ru2en: Sheffield (0) < TRAMECAT (3) < reference (8) = YerevaNN (8) = Huawei United (8)
- zh2en: TRAMECAT (0) < TMT (6) < Alibuba (8) < ai_not_intellegent (10) = OOM (10) = reference (10) < baidu (14) = Wei-Bot (14) = Huawei United (14)

The performance of the reference translations varied from being inferior to all runs that were validated, to being superior to all of them. However, for many language pairs, it was as good as the best runs. We summarize the performance of the reference translation below:

- Inferior to all submissions: en2es
- Superior to one or more submissions: en2de, it2en, zh2en, de2en
- Similar to the best submissions: en2it, en2pt, en2zh, pt2en, fr2en, es2en, ru2en
- Superior to all submissions: en2fr, en2ru

In general, the runs that obtained the best scores in the automatic evaluation were also the ones better ranked in the manual evaluation. We highlight the interesting differences to the automatic evaluation below:

en2es: Even though the UNICAM run obtained a slightly higher BLEU score than the ElhuyarNLP one, the latter was ranked much higher. Further, the Ixamed run was ranked reasonably high, even though it obtained the lowest BLEU score.

en2fr: The nrpu-fjwu run was ranked higher the LIMSI run, even though its BLEU score was slightly lower than the one from LIMSI.

en2zh: The run from Alibuba was ranked together with the highest runs, even though its BLEU score was the second lowest one. The Wei-Bot runs was considered as good as some other ones, even though its BLEU score was considerably higher.

de2en: While we did not observe a large difference in the BLEU scores for the runs, three teams (Huawei United, YerevaNN, NLE) were ranked higher than the other two (UNICAM and TMT).

pt2en: While the Sheffield run obtained a higher BLEU score, runs from the Sheffield and UNICAMP_DL were ranked as similar. However, as stated above, we could not perform a manual validation over a larger set of abstracts.

zh2en: The same differences that we observed for en2zh also occurred for zh2en.

es2en: Even though our evaluation relied on very few abstracts, the results confirmed the ones obtained in the automatic evaluation: all systems seem indeed to have a similar quality.

6.2 Basque abstracts

For the human evaluation of the systems that participated in the English-Basque scientific translation, we only carried out the evaluation at sentence-level. We randomly sampled a total of 100 sentences. The runs that we considered from each team are:

- en2eu (4 teams): DCU-MT (run1), Elhuyar_NLP_team (run2), Ixamed (run3), UTS_NLP (run2)

The results of the human evaluation carried out with Appraise are in Table 23, and like in the MEDLINE evaluation, bold numbers indicate a significance difference between the systems after running a Wilcoxon Signed-Rank test. The final ranking of the systems is as follows:

- en2eu: UTS_NLP (0) < DCU-MT (4) = Ixamed (4) < Elhuyar_NLP_team (10) = reference (10)

Similar to what was observed in the MEDLINE evaluation, ranking of the human evaluation matched the ranking of the automatic evaluation.

7 Discussion

In this section we present insights from the automatic and manual validations. We also reflect on the new processes introduced this year in the workflow of the task.

7.1 Analysis of results and methods

Systems submitted to the biomedical task. Figure 1 shows the correlation between BLEU and chrF scores. The use of the survey was helpful to collect specific features of the systems in order to compare the methods used. However, the variety of resources leveraged by the different teams as well as the variety of information reported about

	TMT-NLE		2	1	4		5	36	9

Table 16: Manual validation for the en2de and de2en of the MEDLINE abstracts test set. The sum of the values for the sentences does not sum up to the expected value for some rows because some sentences might have been skipped. The better performing system (or reference translation) in each pairwise comparison is shown in bold, as well as the respective value that has been identified as superior.

the resources (see Table 7, 8 and 9) make it difficult to directly compare resource use in terms of type or even size. For example, some teams reported the size of their parallel datasets in terms of GB of text, some the number of aligned sentences and sometimes they provided an overall size of resources used for several language pairs.

Biomedical datasets as test suites in the news task. Overall, the best performance on the biomedical datasets was obtained by systems submitted to the biomedical task. These results suggest that domain-specific systems can offer a substantial increase in BLEU score when translating biomedical text. The performance offered by some of the news systems (e.g., Online-B, Online G) was quite high, but it has to be noted that we do not know what training data those system used, and there is no guarantee that our test sentences were not included.

We can also note that whereas no team participated both in the news and biomedical task, we submitted some of our baselines to the news task under the name *WMTbiomedBaseline*. Interestingly, our de2en baseline performed much better there (+2.5 BLEU) on the same text. This is due to supplementary processing: each paragraph to be translated was split into sentences, the sentences were translated one by one, then the results where joined back into a single paragraph. This was not done for the baseline submission to our biomedical translation task, under the assumption that the texts to translate are single-sentence (now invalidated). For the multi-sentence paragraphs, our baselines (as sent to the biomedical task) sometimes contained only the translation of the first sentence, thus leading to a decrease in BLEU score.

7.2 New additions to the workflow of the task

This year, we introduced a number of new processes into the task workflow. First, we performed manual validation of the sentence alignment for three language pairs. This resulted in higher quality alignment, and should be continued. Second, we attempted to split the test sets for the en/fr language

Table 17: Manual validation for the en2es and es2en of the MEDLINE abstracts test set. The sum of the values for the sentences (or abstracts) does not sum up to the expected value for some rows because some sentences (or abstracts) might have been skipped. The better performing system (or reference translation) in each pairwise comparison is depicted in bold, as well as the respective value that has been identified as superior. For es2en, two values are shown: on the left is the validation performed by the English native speaker, and on the right the one from the Spanish native speaker.

pair according to the source language as inferred from MEDLINE metadata. Our experience so far is inconclusive and shows that the initial selection of separate test sets based on source language should be done upstream in the process, as most of the test documents selected had English as the original language. The collection of system information through a survey was effective to collect general comparable information about the systems, especially as the task is growing in number of participants and language pairs offered. However, direct comparison of methods or resources is not necessarily facilitated as authors report information in different ways. A better method for yielding actionable comparisons could be to host a “constrained track" where participants would be requested to use a choice of resources provided in the track.

7.2.1 MEDLINE test sets

We previously presented (cf. Table 2) the results of the manual validation of the automatic alignment that was carried out for the test sets. Here we discuss some of the problems that we found in the automatic alignment for each of the languages.

For all the language pairs, many of the mistakes that we found referred to the titles of the articles, which are usually only available in one of the languages in MEDLINE. Therefore, many of them were correctly aligned to nothing, later identified by the evaluators as being a “NO_ALIGNMENT". However, in some cases, they was incorrectly aligned to the first sentence of the other language, which resulted in them being classified as an “OVERLAP".

The sub-sections which are present in many abstracts, such as “Background" or “Methods" were a cause for trouble. Given their simplicity, they were often correctly aligned. However, in some cases they were aligned to nothing at all (“NO_ALIGNMENT"). In other cases, they were joined to the following or previous sen-

The better performing system (or reference translation) in each pairwise comparison is shown in bold, as well as the respective value that has been identified as superior.

tence and aligned to a sentence in the other language, which did not contain the corresponding sub-section. Such cases were classified as either "SOURCE_GREATER_TARGET", or "TARGET_GREATER_SOURCE".

Comparing one sentence in one language that was automatic aligned to two or more sentences also sometimes caused mistakes. While most of the information is present in both languages, there were always differences between them, and more information in the language for which the alignment tool joined more than one sentence. Depending on the case, the alignment was classified as either "SOURCE_GREATER_TARGET", or "TARGET_GREATER_SOURCE".

Finally some alignments were classified as being "SOURCE_GREATER_TARGET", "TARGET_GREATER_SOURCE", or "OVERLAP"

when small details were present in just one of the languages. For instance, one example lacked the information about the p-value, i.e., "($p < 0.05$)", for one of the languages. For another abstract, the sentence in one language referred to the expression "in the city", while the one in the other language explicitly included the name of the city, i.e., "in Paris". It was common that a variety of small details or additional information which were not equally included for both languages.

7.2.2 Basque Abstracts test set

The alignment between the sentences for the abstracts in Basque and English was also carried out manually. Twelve sentences in Basque lack their translation in English and so these sentences in Basque were removed, resulting in the final test set of 375 pairs. The translations produced by the authors of the abstracts are not literal, and in some cases the information given in both languages is different. For example, in two consecutive sentences in an abstract about the listeriosis disease, we have these sentence pairs: First sentence (sentence 1):

- en: In recent years, we have detected a significant increase in the number of cases in Gipuzkoa.
- eu: *Azken urteotan, Gipuzkoan,* ***listeriosiaren*** *intzidentziaren igoera esanguratsua atzeman da.*
  'In recent years, in Gipuzkoa, there has been a significant increase in the incidence of listeriosis'

Following sentence (sentence 2):

- en: **Listeriosis** is uncommon in the general population, but it is far more frequent in pregnant women and newborns.

Table 23: Manual validation of the en2eu abstracts test set. The better performing system (or reference translation) in each pairwise comparison is shown in bold, as well as the respective value that has been identified as superior.

- eu: *Arrisku- taldeen artean, haurdun dauden emakumeak aurkitzen dira.*
  'Risk groups include pregnant women'

In the first sentence pair, the name of the disease is given in Basque, while in the second pair, the mention is given in English. In the second pair, the sentence in English gives more information than the one in Basque. This fact could well affect the

automatic evaluation.

7.3 Quality of the system translations

We discuss below some of the mistakes that we found during the manual validation of the selected runs and the reference translations.

7.3.1 MEDLINE test sets

en (from de) The quality of the translations has substantially improved since last year, with many instances requiring lengthy manual scrutiny to detect slight nuances in the meaning of the translated texts. In some cases, the subject matter of the abstracts presented a real challenge for the manual validator, as some of the translations required deeper background knowledge of medical procedures and terms to evaluate whether or not the translations from the source language were indeed correct. Examples include: (1) the German term *Hyperandrogenämie* was correctly translated to“hyperandrogenemia" (referring to elevated levels of androgen in the blood) or incorrectly to “hyperandrogenism" (refers to the state characterized by elevated levels of androgens); (2) in the context of liver cirrohsis, the “Child-Pugh-Score" was used as a pro-form term for liver cirrohsis disease severity. In this particular case, the correct translation was not even evident until the abstract was evaluated as a whole, since the manual validation of single sentences did not even contain the term *Child-Pugh-Stadium* in the source German sentence; (3) in an ophthalmology abstract, the German phrase *Aufgrund des ausgeprägten Hornhautödems* was correctly and literally translated in one instance as “Due to the pronounced corneal edema" but slightly differently in the other instance as “Due to the pronounced corneal endothelial epithelial decompensation", which may be partially correct in that corneal edema is a clinical feature of corneal endothelial epithelial decompensation. Such an interpretation would be best evaluated by an opthalmologist.

Abbreviations continue to present difficulties for correct translation. For example, in German, *Cephalosporine der 3. Generation* was never correctly translated to “third generation cephalosporins". Also the disease abbreviation *HEED (Hornhaut-Endothel-Epithel-Dekompensation)* could not be translated into English, though the disease was correctly translated in English to “corneal endothelial epithelial decompensation". The abbreviation for *polyzystische Ovarsyndrom (PCOS)* was incorrectly interpreted as a plural (“PCOs") in one translation.

Some specific medical terms were literally translated from the German source words, but resulted in an unusual or rare choice of words in English. For example, *Darm-Hirn-Achse* literally translated to “bowel-brain axis" instead of “brain-gut axis", *Adipositas* directly to “adiposity" vs. “obesity", *Mikrobiomtransfers* to “microbiome transfer" vs. “microbiota transplantation", *Kupfer-Instrauterinpessar* to “IUP" instead of “intrauterine device (IUD)". In these examples, the translations are in principle still understandable, yet awkward in English.

In some cases, choosing an English synonym of a translated German word altered the original German meaning entirely. For example, the German phrase *abgeschlossenen und laufenden kontrollierten Studien* was translated into “terminated and ongoing controlled trials" as well as “completed and ongoing controlled studies", whereby the use of the adjective “terminated" in this specific context implies that the clinical trial was prematurely stopped, possibly due to ethical, financial, safety or efficacy concerns. In this context, “completed" is the better adjective, as it implies that a study protocol was carried out to its scheduled endpoints. Similarly, in the context of raising children, the German *Erziehungserfahrungen* was sometimes translated to “educational experience", rather than the correct term “parenting experiences".

es (from en) This year, five different MT systems competed against the human reference translation for the English to Spanish language pair. The overall quality of all five systems was very good this year, when comparing sentences, being equal to the human translation in many instances.

The handling of acronyms still requires improvement for some of the MT systems, as the treatment vary from inconsistent translation, in the case of abstracts, to wrong use of lower case instead of capital letters as in the following example, correct acronym for *Sistema Único de Salud* (*SUS*) versus *Sistema Único de Salud* (*sus*). There were also some instances of literal translation of terms such as the mistranslation of *severe temperature* as *temperatura severa* when a more correct translation would have been *temperatura grave*.

In long sentences, there were also cases of missing information in the MT systems that affected the overall quality of the translations. In the rare cases where there were no clear issues with the

MT output, the human translation was sometimes more readable and more fluent and therefore the preferred choice in terms of quality. As in the following example:

- Original English text: *The objective was to assess parental knowledge, behaviors, and fears in the management of fever in their children.*
- Tramecat Translation: *El objetivo fue evaluar el conocimiento, comportamientos y miedos de los padres en el manejo de la fiebre en sus hijos.*
- Reference translation: *El objetivo fue evaluar los conocimientos, actitudes y temores de los padres ante la fiebre de sus hijos.*

The noun group elements have greater concordance in the reference translation rendering it more readable and fluent than the tramecat MT system. When comparing the reference abstracts to the MT abstracts, the human translation had higher quality due to its consistency and overall textual coherence. Some systems had issues with term translation consistency, non-fluent text (rare) or missing information (also rare). As mentioned, the MT systems performed very well when compared with one another and with the reference translation, to obtain a good level of quality, but in some cases many of the systems would still require human intervention in terms of post-edition to improve them to publishing quality level.

en (from fr) The overall quality of translations was high, with many perfect translations. Most translation issues arose from unknown vocabulary or an inappropriate use of vocabulary in context. This includes (i) the presence of untranslated French words (*We montrons* as a translation of *nous montrons* 'we show'), (ii) the erroneous translation of subword units, resulting in a merging of units (*tharural* instead of *than rural*), (iii) erroneous translation of context-dependent ambiguous terms (*Study of litter* as a translation of *étude de portée* 'scoping study' as a consequence of a poor translation of the ambiguous word *portée* 'scope, litter (of puppies)') and (iv) a strange translation of unseen source words that may nevertheless share initial subword units with the predicted word (*consumptions of cruels* as a translation of *consommation de crudités* 'consumption of raw vegetables'). A further issue noted was the poor translation of the French pronoun *il* 'it/he' into *he* when this refers to the article itself. The correct translation of these pronouns necessitates taking into account preceding context.

en (from it) The quality of the translations was neatly divided between almost-perfect and very poor, and this is reflected in the relative rankings between validations reported in Table 19. Outright errors in the good translations were rare; occasionally, the subject of a subordinate clause was mistaken. Interestingly, some translations proved capable of appropriately using synonyms and correctly rendering the meaning of the source with a slightly less literal and more idiomatic translation.

en (from zh) The quality of the translations is generally good. Some systems produced translations that provided not only correctness but also more typical English word usage beyond a literal translation. As an example, 不同性别、年龄别和身高别儿童青少年血压评价 was translated more literally by one system as *blood pressure evaluation in children and adolescents of different sexes, ages and heights*, but another system was able to produce a more natural translation: *blood pressure evaluation in children and adolescents by gender, age and height*.

The biggest source of errors is by far the translation of biomedical concepts. Presumably because a concept is not available in a reference dictionary in the target language, the translation systems often resorted to a literal interpretation of the source characters, leading to a translation that ranged from comprehensible to completely incorrect. For instance, a correct translation for 美观协调 is *aesthetic coordination* (in the context of teeth and jaw operations), but an actual and rather literal translation was *good and beautiful are in harmony*, which was still comprehensible. In another example, however, a correct translation of 早期移植物功能不全 was *early graft dysfunction*, but an incorrect translation yanked two characters 植物 (meaning "plants") out of the 3-character term 移植物 (meaning "transplant matter") and produced *early removal of plant functions*, which was completely incorrect.

A second problem area is the skipping of source words or even phrases. For biomedical texts, even skipping one critical word can significantly alter the context of the entire text. Take 老年骨质疏松人群 as an example, whose full translation is *elderly osteoporosis population*. Some translations

omitted the word *elderly*, and that changed the context of the corresponding scientific study.

fr (from en) Overall, the quality of the translations ranged from fair to good and was improved over previous editions of the task. Some aspects previously noted as difficult (e.g., co-reference, acronym definitions) were correctly translated by some of the systems at the sentence level. However, the abstract-level evaluation evidenced overall consistency issues. For example, a procedure correctly described as *cholécystectomie laparoscopique conventionnelle (CLC)* in an introductory sentence could be referred to with a different acronym , e.g., *CCC* in sentences appearing later in the same abstract. Other issues noted in previous editions remained, such as repeated portions of text (up to 96 repetitions of a word pair in one evaluated sentence) and untranslated sections, especially in passages containing complex numerical data. Some issues with technical vocabulary also led to incorrect translations. In the comparison of translation issues exhibited by different systems in the same sentence, a preference was given to medical correctness over grammatical correctness. For example, when comparing:

- Translation A: *L'étude en microscopie multiphotonique montre que,* ***comme on le attendait****, l'émiline-1* ***se colocalise*** *avec l'élastine.*

  and

- Translation B: *L'étude de microscopie multiphotonique montre que,* ***comme attendu****, l'Emiline-1* ***permet de colorer*** *avec de l'Éastine.*

where *comme attendu* (B) is grammatically preferable to *comme on le attendait* (A) as a translation of *as expected* and *se colocalise* (A) is semantically preferable to *permet de colorer* (B) as a translation of *colocalizes*, translation A is assessed as superior to translation B even though neither translation is perfect.

it (from en) The quality of the translations was strongly influenced by the systems (unknown at the time of the evaluation). Some of the translations were almost perfect and the best system was also able to use the correct technical terminology for specialized domains, such as philosophy and medicine. Other translation were partially correct, in the sense that they were understandable but with syntactic or lexical inconsistencies. For example, the term "otherness"– meaning "being different" – was incorrectly translated by the term *estraneità* (meaning "unfamiliarity") rather than the Italian equivalent *alterità*, which conveys the same meaning. Another example specific for the medical domain is the translation of the multi-word unit "visceral adhesions" by *adesivo viscerale* ("visceral sticker" as a literal translation) rather than the correct Italian equivalent *aderenze viscerali*. Finally, some other translations presented non-existent Italian words.

en (from pt) The translations have high fidelity to the source texts, but in terms of natural language style and typical word usage, the translations are clearly lacking, especially in longer sentences. There was a small number of critical errors in translating biomedical concepts, rendering the translation incomprehensible. For example, *acidentes ofídicos* was correctly translated as *snakebite* or as a more pedantic version, *snakebite envenomations*, but one incorrect translation *obscene accidents* was too obscure to hint at the original term. Lexical similarity might have been a contributing factor to errors as well. *Ofidismo* (meaning "snakebite") was translated as *ophidism* (meaning "poisoning caused by snake venom"), which was not an exact translation but still highly relevant. However, an incorrect translation *oblivinism* was, to the best of our knowledge, not an English word.

pt (from en) The translations have improved but none of the texts were perfect, since we also found mistakes in the reference translations. One of the most significant improvements, in comparison to previous years, is the lack of untranslated words; only very few of them were observed. However, one of the frequent problems still remains: poor translations of the acronyms, which are often the ones from the English (source) text. Most of the errors were actually in the small details, such as the best choice of words for a particular concept (e.g., *o processo de morte e morte* as a translation of *process of death and dying*), gender or number coordination (e.g., *na encaminhamento dos pacientes*, *programa de formação específico*), or misplacement of commas. Finally, more errors occurred in longer sentences due to their increased complexity than shorter ones, which tended to be correct.

de (from en) The overall quality of translation was high. In various cases the better translations were chosen based on small nuances, such as no capitalization errors, better ordering of words or sentence structure that sounds slightly more natural to a native speaker. Considering the original German abstracts, sentences often appeared to be freely translated, targeting an identical meaning rather than an exact translation. Therefore, in various cases, the automatic translations outperformed the reference translations, which sometimes lacked some information.

Generally the translation of acronyms appears more difficult. In multiple cases, translations used the English acronym instead of the German version, although the underlying term itself has been translated correctly. Finally we observed that some translations favored very technical terms, while others favored rather simple ones, but both correct. In those cases it is difficult to choose the better translation, if the rest of the sentences have the same quality. Generally we believe that using more complicated words does not mean that the translation of a scientific paper is necessarily better.

zh (from en) While the quality of zh2eh translations (discussed above) was already generally good, the quality of en2zh translations was generally even better in comparison.

Where applicable, a very specific term in English can be left untranslated in English in the Chinese text with good effect. Protein names such as *CD34* and long, complicated chemical names with abbreviations are prominent examples. The participating systems employed different strategies here: some repeated only the original English term, some repeated the English term as well as translated it in Chinese, and some translated it in Chinese but appended the English abbreviation.

In terms of language style, some systems produced more natural Chinese word usage than a literal translation. Take *evidence is strongest* as an example. A correct but linguistically clumsy translation was 证据最强, which means exactly "evidence is strongest." But other systems were able to produce more typical wordings such as 证据最有力 (meaning "evidence has most force") or, even better, 证据最为充分 (meaning "evidence is most sufficient").

The translation of biomedical concepts was again the biggest source of error, and again the problematic translations ranged from comprehensible to completely incorrect. For instance, *positive control* in the context of conducting experiments should be correctly translated as 阳性对照, but some system instead produced 积极的控制, which means "positively or enthusiastically take charge." Some translations were outright incorrect, such as when a simple term *fever* was translated as 百日咳, which means "whooping cough."

en (from ru) The English-Russian task was offered for the first time, with four MT systems participating and competing against the reference translation. The quality of translations were generally good, with two systems producing significantly better results. Translations frequently contained synonyms successfully carrying on the meaning of the source sentence. For example, "травматические поражения" is correctly translated as "traumatic lesions" and "traumatic injury". Observed was a range of translations, where some presented a stylistically more elegant solution then the others. For example, the phrase "reduction of pain syndrome" is better expressed as "reduce the level of pain". There was a small number of errors related to incorrect translation of biomedical key terms, resulting in translation being impractical. A mild example of incorrectly translated terminology is "spinal surgeon" instead of "spinal surgery". Skipping over segments of sentence was observed mainly in sentences with challenging tokenization.

ru (from en) The Russian-English task was offered for the first time, with four MT systems participating and competing against the reference translation. The quality of translations were generally good, with two systems producing significantly better results. Abbreviated disease names tended to cause an issue in translation. Sentences containing definition and the first mention of abbreviation contained the correct abbreviation. In subsequent sentences, the abbreviation was getting transliterated. For example, "chronic endometritis (CE)" is translated as "хроническим эндометритом (ХЭ)". However subsequent sentences refer to "CE" as "КЭ" and not as "ХЭ". Rarely observed were instances with the meaning lost in translation. For example, the source sentence "The biological age of sleep apnea patients exceeded the passport age by 41.3% and comorbid patients by 49.6%." was translated as: "Биологический возраст пациентов с апнозом сна превышал пассажиров на 41.3%, а сопутствующих на 49.6%."

7.3.2 Basque abstracts

The BLEU scores for this subtask are given in Table 14. We have to consider that BLEU scores tend to be low when translating into Basque (Jauregi Unanue et al., 2018), and this can be seen in the results. The best performing system in the automatic evaluation was Elhuyar_NLP, with a BLEU score of 0.1279. Ixamed and DCU-MT have similar performance, with UTS_NLP achieving the lowest BLEU score. In spite of the low BLEU scores, the manual evaluation in Table 23 showed that Elhuyar_NLP was competitive against the reference translation, and was preferred to other systems.

During the manual evaluation, the annotators also observed that sometimes the system produced output in Spanish instead of Basque. This was obviously a mistake when using Spanish as a pivot language, but it may have helped the BLEU scores in some cases, due to shared terminology. In the manual annotation, text in Spanish was penalized.

7.3.3 Basque terminology

As explained in Section 2.2.1, the development set and test set were the same, and this caused the results to be higher than in a real setting.[22] The results in Table 15 show that most systems performed with high accuracy and BLEU scores. Elhuyar_NLP was again the highest performer, with Ixamed producing very low scores, perhaps due to an error in their submission. We did not perform manual evaluation for this subtask.

8 Conclusions

We presented the findings of the fifth edition of the WMT biomedical task. This edition addressed three new languages and test sets that included scientific abstracts and terminologies. We explored news ways of improving our tests and carried out (as in previous editions of the task) both an automatic and a manual validation. Results confirmed the improvements of the runs and for some language pairs, suggested that some runs were on a par with or superior to the reference translations.

Acknowledgments

We would like to thank all participants in the challenges, and especially those who supported us for the manual evaluation.

[22] As a reference, one of the participating systems (UTS_NLP) was able to re-run their system over the real test set. The performance drop was 0.08 for accuracy (from 0.73 to 0.65), and 0.05 for BLEU (from 0.71 to 0.66).

Abstract

This paper presents the results of the WMT20 Metrics Shared Task. Participants were asked to score the outputs of the translation systems competing in the WMT20 News Translation Task with automatic metrics. Ten research groups submitted 27 metrics, four of which are reference-less "metrics". In addition, we computed five baseline metrics, including SENTBLEU, BLEU, TER and CHRF using the SacreBLEU scorer. All metrics were evaluated on how well they correlate at the system-, document- and segment-level with the WMT20 official human scores.

We present an extensive analysis on influence of reference translations on metric reliability, how well automatic metrics score human translations, and we also flag major discrepancies between metric and human scores when evaluating MT systems. Finally, we investigate whether we can use automatic metrics to flag incorrect human ratings.

1 Introduction

The metrics shared task[1] has been a key component of WMT since 2008, serving as a way to validate the use of automatic MT evaluation metrics and drive the development of new metrics.

We evaluate automatic metrics that score MT output by comparing them with a reference translation generated by human translators, who are instructed to translate "from scratch", without post-editing from MT. In addition, following last year's collaboration with the WMT Quality Estimation (QE) task, we also invited submissions of reference-free metrics that compare MT outputs directly with the source segment.

Similar to the last year's editions, the source, reference texts, and MT system outputs for the metric task come from the News Translation Task (Barrault et al., 2020, which we denote as Findings 2020). This year, the language pairs were English ↔ Chinese, Czech, German, Inuktitut, Japanese, Polish, Russian and Tamil. We further included systems participating in the WMT parallel corpus filtering task (Koehn et al., 2020): Khmer and Pashto to English.[2]

All metrics are evaluated based on their agreement with human evaluation. We evaluate metrics at three levels: comparing MT systems on the entire testset, segments (either sentences or short paragraphs), and new this year, documents. We introduce document-level evaluation to incentivize the development of metrics that are take into account broader context of evaluated sentences or paragraphs, following the recent emergence of document-level MT techniques.

Multiple References This year, we have two independently generated references for English ↔ German, English ↔ Russian, and Chinese → English. This lets us investigate the influence of references and the utility of multiple references. We instructed participants to score MT systems against the references individually as well as with all available references. In addition, we also supplied a set of references for English to German, that were generated by asking linguists to paraphrase the WMT reference as much as possible (Freitag et al., 2020). These references are designed to minimise translationese in the reference which could lead to metrics to be biased against systems that generate more natural text.

[1] http://www.statmt.org/wmt20/metrics-task.html

[2] Note that the metrics task inputs also included MT systems translating between German ↔ French in the News Translation Task, and English → Khmer and Pashto from the WMT parallel corpus filtering task. We are unable to evaluate metrics on these language pairs as human evaluation is not available

Proceedings of the 5th Conference on Machine Translation (WMT), pages 688–725

Evaluating Human Translations Given that we have multiple human translations, we asked participants to evaluate each human translation using the other as a reference. For these language-pairs, at least one of these human translations was included in the human evaluation, so we can directly evaluate metrics on how they rank the human translation compared to the MT systems.

Additional Human Evaluation Finally, we pose the question if some of the discrepancies between metrics and human scores can be explained by bad human ratings. We rerun some of the human evaluations by using the same template, but switching the rater pool from non-experts to professional linguists. In particular, we rerun human evaluation for a subset of translations where all metrics disagree with the WMT human evaluation. This experiment could reveal a new use case of automatic metrics and indicate that automatic metrics can be used to identify bad ratings in human evaluations.

We first give an overview of the task (Section 2) and summarize the baseline (Section 3.1) and submitted (Section 3.2) metrics. The results for system-, segment-, and document-level evaluation are provided in Sections 4, followed by a joint discussion Section 5. Section 6 describes our rerunning of human evaluation with linguists before we summarise our findings in Section 7.

We will release data, code and additional visualisations in the metrics package to be made available at http://www.statmt.org/wmt20/results.html

2 Task Setup

This year, we provided task participants with one test set for each examined language pair, i.e. a set of source texts (which are commonly ignored by MT metrics), corresponding MT outputs (these are the key inputs to be scored) and one or more reference translations.

In the system-level, metrics aim to correlate with a system's score which is an average over many human judgments of segment translation quality produced by the given system. In the segment-level, metrics aim to produce scores that correlate best with a human ranking judgment of two output translations for a given source segment. And finally, we also trial document-level evaluation this year. (more on the manual quality assessment in Section 2.3).

Segments are sentences for all language pairs except English ↔ German and Czech, and for English → Chinese, which do not contain sentence boundaries and are translated and evaluated at the paragraph-level.

Participants were free to choose which language pairs and tracks (system/segment/document and reference-based/reference-free) they wanted to take part in.

2.1 Source and Reference Texts

The source and reference texts we use are mainly sourced from this year's WMT News Translation Task (see Findings 2020).

The test set typically contains somewhere between 1000 and 2000 segments for each translation direction, with fewer segments for some paragraph-segmented test sets, and the English ↔ Inuktitut directions contain 2971 sentences.

All test sets are from the news domain, except the English ↔ Inuktitut datasets which have a mix of in-domain text from Canadian Parliament Hansards (1566 sentences) and out-of-domain news documents (1405 sentences).

We also have systems from the parallel corpus filtering task which are from the Wikipedia domain (also labelled *newstest2020* in the metrics test set). The Khmer → English and Pashto → English contain 2320 and 2719 sentences respectively.

The reference translations provided in *newstest2020* were created in the same direction as the MT systems were translating. The exceptions are English ↔ Inuktitut, Khmer → English and Pashto → English, where the testset is a mixture of "source-original" and "target-original" texts.

2.2 System Outputs

The results of the Metrics Task are affected by the actual set of MT systems participating in a given translation direction. On one hand, if all systems are very close in their translation quality, then even humans will struggle to rank them. This in turn will make the task for MT metrics very hard. On the other hand, if the task includes a wide range of systems of varying quality, correlating with humans should be generally easier. One can also expect that if the evaluated systems are of different types, they will exhibit different error patterns and various MT metrics can be differently sensitive to these patterns.

- **Parallel Corpus Filtering Task.** This task required participants to submit scores for each sentence in the provided noisy parallel texts. These scores were used to subsample sentence pairs, which was then used to train a neural machine translation system (fairseq). This was tested on a held-out subset of Wikipedia translations.

- **Regular News Tasks Systems.** These are all the other MT systems in the evaluation; differing in whether they are trained only on WMT provided data ("Constrained", or "Unconstrained") as in the previous years.

With all language pairs, in addition to the submissions to the task, the test sets also include translations from freely available web services (online MT systems), which are deemed unconstrained.

Overall, the results are based on 208 systems across 18 language pairs.

2.3 Manual Quality Assessment

Human scores were obtained using Direct Assessment, where annotators are asked to rate the adequacy of a translation compared to either the source segment or a reference translation of the same source. This year, human data was collected from reference-based evaluations (or "monolingual") and reference-free evaluations (or "bilingual"). The reference-based (monolingual) evaluations were crowdsourced, while the reference-less (bilingual) evaluations were mainly from MT researchers who committed their time to contribute to the manual evaluation for each submitted system to the translation task.

Finally, following reports that MT system translations might seem adequate when scored in isolation but not in context of the whole document, when possible, the ratings are collected for each segment with document context. Table 1 summarises the details of how human annotations were collected for various language-pairs at WMT 2020.

The English → Inuktitut dataset, which contains a mix of in-domain (Hansard) and out-of-domain (news) data, was only evaluated on out-of-domain segments, so for system level evaluation, we evaluate metric scores computed on the news domain only as well as the full test set.

See Findings 2020 for details on human evaluation.

2.3.1 System-level Golden Truth: DA

For the system-level evaluation, the collected continuous DA scores, standardized for each annotator, are averaged across all assessed segments for each MT system to produce a scalar rating for the system's performance.

The underlying set of assessed segments is different for each system. Thanks to the fact that the system-level DA score is an average over many judgments, mean scores are consistent and have been found to be reproducible (Graham et al., 2013). For more details see Findings 2020.

The score of an MT system is calculated as the average rating of the segments translated by the system.

2.3.2 Segment-level Golden Truth: DARR

Starting from Bojar et al. (2017), when WMT fully switched to DA, we had to come up with a solid golden standard for segment-level judgements. Standard DA scores are reliable only when averaged over sufficient number of judgments.[3]

Fortunately, when we have at least two DA scores for translations of the same source input, it is possible to convert those DA scores into a relative ranking judgement, if the difference in DA scores allows conclusion that one translation is better than the other. In the following, we denote these re-interpreted DA judgements as "DARR", to distinguish it clearly from the relative ranking ("RR") golden truth used in the past years.[4]

From the complete set of human assessments collected for the News Translation Task, all possible pairs of DA judgements attributed to distinct translations of the same source segment were converted into DARR better/worse judgements. Distinct translations of the same source input whose DA scores fell within 25 percentage points (which could have

[3]For segment-level evaluation, one would need to collect many manual evaluations of the exact same segment as produced by each MT system. Such a sampling would be however wasteful for the evaluation needed by WMT, so only some MT systems happen to be evaluated for a given input segment. In principle, we would like to return to DA's standard segment-level evaluation in future, where a minimum of 15 human judgements of translation quality are collected per translation and combined to get highly accurate scores for translations, but this would increase annotation costs.

[4]Since the analogue rating scale employed by DA is marked at the 0-25-50-75-100 points, we use 25 points as the minimum required difference between two system scores to produce DARR judgements. Note that we rely on judgements collected from known-reliable volunteers and crowd-sourced workers who passed DA's quality control mechanism. Any inconsistency that could arise from reliance on DA judgements collected from low quality crowd-sourcing is thus prevented.

Language pairs	source/reference	crowd/researcher	document context
iu-en	reference	crowd	No
*-en except iu-en	reference	crowd	Yes
en-*, de-fr, fr-de	source	mix of crowd and researcher*	Yes

Table 1: Direct Assessment at WMT20. Note that researcher annotations can contain some amount of professional annotations

been deemed equal quality) were omitted from the evaluation of segment-level metrics. Conversion of scores in this way produced a large set of DARR judgements for all language pairs, shown in Table 2 due to combinatorial advantage of extracting DARR judgements from all possible pairs of translations of the same source input. We see that only km-en and ps-en can suffer from insufficient number of these simulated pairwise comparisons.

The DARR judgements serve as the golden standard for segment-level evaluation in WMT19.

2.3.3 Document-level Golden Truth: DARR

As segments were scored in document context, we can compute document scores as the average human rating of the segments in the document. We acknowledge that this may be an oversimplification. First of all, we are hoping that human assessors have indicated errors in document-level coherence at at least one of the affected segments, but we have no evidence that they actually do so. Second, document-level phenomena are rather scarce and averaging segment-level scores is likely to average out these sparse observations even if they were marked at individual sentences. And lastly, in some situations, lack of cross-sentence coherence can be so critical that any strategy of composing sentence-level scores is bound to downplay the severity of the error, see e.g. Vojtěchová et al. (2019). At the current point, we have nothing better to start with but we believe that better techniques will be proposed in the future.

Graham et al. (2017) recommend around averaging 100 annotations per document to obtain reliable document scores. Since the average number of assessments we have is much less than that, we compute the ground truth in the same way as the segment level evaluation.

We first compute document scores as the average of all segment scores in the document, which we denote as DOC-DA. We then generate DOC-DARR pairs of better and worse translations of the same source document when there is at least a 25 point difference in the raw DOC-DA scores. See Table 3 for details.

In case of DARR (which we denote as DOC-DARR), all language pairs suffer from insufficient number of these simulated pairwise comparisons.

Similar to segment-level evaluation, we use the Kendall Tau-like formula (Section 2) to evaluate metric agreement with humans on the generated pairwise DARR judgements.

Note that we do not include any human-translated segments in this evaluation. In addition, iu-en is excluded from document-level evaluation because its DA judgements were collected for isolated sentences.

3 Metrics

3.1 Baselines

We agree with the call to use SacreBLEU (Post, 2018) as the standard MT evaluation scorer. We no longer report scores of the metrics from the Moses scorer, which requires tokenized text. We use the following metrics from the SacreBLEU scorer as baselines, with the default parameters:

3.1.1 SacreBLEU baselines

- BLEU (Papineni et al., 2002a) is the precision of n-grams of the MT output compared to the reference, weighted by a brevity penalty to punish overly short translations. `BLEU+case.mixed+lang.LANGPAIR+numrefs.1+smooth.exp+tok.13a+version.1.4.14`

  We run SacreBLEU with the `--sentence-score` option to obtain sentence scores for SENTBLEU; this uses the same parameters as BLEU. Although not it's intended use, we also compute system- and document-level scores for SENTBLEU as the mean segment score.

- TER (Snover et al., 2006) measures the number of edits (insertions, deletions, shifts and substitutions) required

	DA>1	Ave	DA pairs	DARR

Table 3: Document-level: Number of judgements for DOC-DA converted to DOC-DARR data; "DOC-DA>1" is the number of source input documents in the manual evaluation where we have DOC-DA scores for at least two translations of that same source input documents; "Ave" is the average number of translations with at least one DOC-DA judgement available for the same source input document; "DOC-DA pairs" is the number of all possible pairs of translations of the same source input resulting from "DOC-DA>1"; and "DOC-DARR" is the number of DOC-DA pairs with an absolute difference in DOC-DA scores greater than the 25 percentage point margin.
Note that iu-en is not included as document-context was not available for this evaluation.

to transform the MT output to the reference. `TER+lang.LANGPAIR-+tok.tercom-nonorm-punct-noasian-uncased+version.1.4.14`

- CHRF (Popović, 2015) uses character n-grams instead of word n-grams to compare the MT output with the reference [5]. Version string: `chrF2+lang.LANGPAIR-+numchars.6+space.false-+version.1.4.14`.

3.1.2 CHRF++

CHRF++ (Popović, 2017) includes word unigrams and bigrams in addition to character ngrams. We ran the original Python implementation of the metric [6] with the default parameters `--ncorder 6 --nwworder 2 --beta 2`

3.2 Submissions

The rest of this section summarizes participating metrics.

3.2.1 BERT-BASE-L2, BERT-LARGE-L2, MBERT-L2

The three baselines were obtained by fine-tuning BERT (Devlin et al., 2019) on the ratings of WMT Metrics years 2015 to 2018, using a regression loss. What distinguishes the metrics is the initial BERT checkpoint: BERT-BASE-L2 uses a 12-layer Transformer architecture pre-trained on English data, MBERT-L2 is similar but trained

[5] Note that the SacreBLEU scorer does not yet implement CHRF with multiple references

Table 4: Participants of WMT20 Metrics Shared Task. "•" denotes that the metric took part in (some of the language pairs) of the segment- and/or document- and/or system-level evaluation. "⊘" indicates that the document- and system-level scores are implied, simply taking arithmetic (macro-)average of segment-level scores. "–" indicates that the metric didn't participate the track (Seg/Doc/Sys-level). "⋆" indicates that we computed the metric's document or system score for this track as the macro-average of segment scores, though the metric is not defined this way. A metric is learned if it is trained on a QE or metric evaluation dataset (i.e. pretraining or parsers don't count, but training on WMT 2019 metrics task data does).

on Wikipedia data in 102 languages, and BERT-LARGE-L2 is English-only with 24 layers.

3.2.2 BLEURT, BLEURT-EXTENDED, YISI-COMBI, BLEURT-YISI-COMBI

BLEURT (Sellam et al., 2020a) is a BERT-based regression model trained twice: first on million synthetic pairs obtained by random perturbations, then on ratings from years 2015 to 2019 of the WMT Workshop. BLEURT-EXTENDED (Sellam et al., 2020b) is a BERT-based regression model trained on human ratings of years 2015 to 2019 of the WMT Workshop, combined with BERT-Chinese for to-Chinese sentence pairs. The main checkpoint is a 24-layer Transformer, trained on a mixture of Wikipedia articles and training data from WMT Newstest in 20 languages.

YISI-COMBI: We are using YISI-1 on an mBERT model that is fine tuned on WMT data for single reference submissions. We are using aggregating internal scores in YISI over different references for the final output for multi reference submission.

BLEURT-COMBI: We are using the same output as YISI-COMBI for single reference submissions. We are mixing YISI-1, YISI-2 and BLEURT scores for different references for the multi reference submission.

3.2.3 CHARACTER

CHARACTER (Wang et al., 2016), identical to the 2016 setup, is a character-level metric inspired by the commonly applied translation edit rate (TER). It is defined as the minimum number of character edits required to adjust a hypothesis, until it completely matches the reference, normalized by the length of the hypothesis sentence. CHARACTER calculates the character-level edit distance while performing the shift edit on word level. Unlike the strict matching criterion in TER, a hypothesis word is considered to match a reference word and could be shifted, if the edit distance between them is below a threshold value. The Levenshtein distance between the reference and the shifted hypothesis sequence is computed on the character level. In addition, the lengths of hypothesis sequences instead of reference sequences are used for normalizing the edit distance, which effectively counters the issue that shorter translations normally achieve lower TER. Similarly to other character-level metrics, CHARACTER is generally applied to nontokenized outputs and references, which also holds for this year's submission with one exception. This year tokenization was carried out for en-ru hypotheses and references before calculating the scores, since this results in large improvements in terms of correlations. For other language pairs, no tokenizer was used for pre-processing.

3.2.4 COMET

COMET* metrics (Rei et al., 2020b) were build using the Estimator model or the Translation Ranking model proposed in Rei et al. (2020a). Those neural models use XLM-RoBERTa to encode source, MT hypothesis and reference in the same cross-lingual space and then are optimised towards different objectives. COMET (main metric) is an Estimator model that regresses on Direct Assessments (DA) from 2017 to 2019 and COMET-2R is a variant of COMET (main metric) that was trained to handle multiple references at inference time. COMET-HTER and COMET-MQM follow the same architecture but regress on Human-mediated Translation Edit Rate (HTER) and a proprietary metric compliant with the Multidimensional Quality Metrics framework (MQM), respectively. COMET-Rank uses the Translation Ranking architecture to directly optimize the distance between "better" hypothesis and the respective source and reference, while pushing the "worse" hypothesis away. This Translation Ranking model was directly optimised on DA relative-ranks from 2017 to 2019. Finally, COMET-QE removes the reference at input and proportionately reduces the dimensions of the estimator network to accommodate the reduced input.

3.2.5 EED

EED (Stanchev et al., 2019) is a character-based metric, which builds upon CDER. It is defined as the minimum number of operations of an extension to the conventional edit distance containing a "jump" operation. The edit distance operations (insertions, deletions and substitutions) are performed at the character level and jumps are performed when a blank space is reached. Furthermore, the coverage of multiple characters in the hypothesis is penalised by the introduction of a coverage penalty. The sum of the length of the reference and the coverage penalty is used as the normalisation term.

3.2.6 MEE

MEE (Ananya Mukherjee and Sharma, 2020) is an automatic evaluation metric that leverages the similarity between embeddings of words in candi-

date and reference sentences to assess translation quality. Unigrams are matched based on their surface forms, root forms and meanings which aids to capture lexical, morphological and semantic equivalence. Semantic evaluation is achieved by using pretrained fasttext embeddings provided by Facebook to calculate the word similarity score between the candidate and the reference words. MEE computes evaluation score using three modules namely exact match, root match and synonym match. In each module, fmean-score is calculated using harmonic mean of precision and recall by assigning more weight to recall. The final translation score is obtained by taking average of fmean-scores from individual modules.

3.2.7 ESIM

Enhanced Sequential Inference Model (Chen et al., 2017) is a neural model proposed for Natural Language Inference that has been adapted for MT evaluation by Mathur et al. (2019). It uses cross-sentence attention and sentence matching heuristics to generate a representation of the translation and the reference, which is fed to a feedforward regressor. This year's scores were submitted by Bawden et al. (2020) as part of the submission on PARESIM.

3.3 OPENKIWI-BERT, OPENKIWI-XLMR

OPENKIWI-BERT and OPENKIWI-XLMR (Kepler et al., 2019) are state of the art Quality Estimation models developed for the WMT20 QE shared task and are trained with WMT Metrics data from 2017 to 2019.

3.3.1 PARBLEU, PARCHRF++, PARESIM

PARBLEU, PARCHRF++, and PARESIM (Bawden et al., 2020) are variants of their respective core metrics computed against the provided human reference and a set of automatically generated paraphrases. PARBLEU used five paraphrases, while the other two used only one. Both BLEU and CHRF++ have in-built support for multiple references. For ESIM, we calculate the score for each reference separately and then average them to get the final score.

3.3.2 PRISM

PRISM (Thompson and Post, 2020) is a many-many multilingual neural machine translation system trained on data for 39 language pairs, with data derived largely from WMT and Wikimatrix. It casts machine translation evaluation as a zero-shot paraphrasing task, producing segment-level scores by force-decoding between a system output and a reference, in both directions, and averaging the model scores. System-level scores are produced by averaging segment-level ones. For evaluation in Inuktikut, Khmer, Pashto, and Tamil, we used a "Prism44" model that was retrained after adding WMT-provided data for these languages to its original training data set. All other languages were evaluated with the original "Prism39" model.

3.3.3 SWSS+METEOR

SWSS (Semantically Weighted Sentence Similarity, Xu et al. 2020) is an approach to extracting semantic core words, which are words that carry important semantic meanings in sentences, and using them in MT evaluation. It uses UCCA (Universal Conceptual Cognitive Annotation), a semantic representation framework, to identify semantic core words, and then calculates sentence similarity scores on the overlap of semantic core words of sentence pairs. Taking sentence-level semantic structure information into consideration, SWSS can improve the performance of lexical metrics when combined with them. The submitted metric (SWSS+METEOR) is a weighted combination of SWSS and Meteor.

3.3.4 YISI-0, YISI-1, YISI-2

YISI (Lo, 2019, 2020) is a unified semantic MT quality evaluation and estimation metric for languages with different levels of available re-sources. YISI-1 is a reference-based MT evaluation metric that measures the semantic similarity between a ma-chine translation and human references by aggregating the idf-weighted lexical semantic similarities based on the contextual embeddings extracted from pretrained language models (BERT, CamemBERT, RoBERTa, XLM, XLM-RoBERTa, etc.) and optionally incorporating shallow semantic structures (denoted as YISI-1_SRL; not participating this year). YISI-0 is the degenerate version of YISI-1 that is ready-to-deploy to any language. It uses longest common character substring to measure the lexical similarity. YISI-2 (Lo and Larkin, 2020) is the bilingual, reference-less version for MT quality estimation, which uses bilingual mappings of the contextual embeddings extracted from pretrained language models (XLM or XLM-RoBERTa) to evaluate the crosslingual lexical semantic similarity between the input and

MT output. Like YISI-1, YISI-2 can exploit shallow semantic structures as well (denoted as YISI-2_SRL; does not participate this year).

3.4 Pre-processing

Since some metrics, such as BLEU, aim to achieve a strong positive correlation with human assessment, while error metrics, such as TER, aim for a strong negative correlation, in previous years we compare metrics via the absolute value $|r|$ of a given metric's correlation with human assessment. However, this can mask instances of true negative correlation for metrics that aim for a positive correlation (and vice-versa).

For system, document and segment level scores, we reverse the sign of the score of error metrics prior to the comparison with human scores, whether on the system, document or segment level: higher scores have to indicate better translation quality.

4 Results

4.1 System-Level Evaluation

As in previous years, we employ the Pearson correlation (r) as the main evaluation measure for system-level metrics. The Pearson correlation is as follows:

$$r = \frac{\sum_{i=1}^{n}(H_i - \overline{H})(M_i - \overline{M})}{\sqrt{\sum_{i=1}^{n}(H_i - \overline{H})^2}\sqrt{\sum_{i=1}^{n}(M_i - \overline{M})^2}} \quad (1)$$

where H_i are human assessment scores of all systems in a given translation direction, M_i are the corresponding scores as predicted by a given metric. $\overline{H}$ and $\overline{M}$ are their means, respectively.

As recommended by Graham and Baldwin (2014), we employ Williams significance test (Williams, 1959) to identify differences in correlation that are statistically significant. Williams test is a test of significance of a difference in dependent correlations and therefore suitable for evaluation of metrics. Correlations not significantly outperformed by any other metric for the given language pair are highlighted in bold in all the results tables that show Pearson correlation of metric and human scores.

Pearson correlation is ideal for reporting whether metric scores have the same trend as human scores. In practice, we use metrics to make decisions comparing MT systems, and Kendall's Tau appears to be more close to this use case, as it directly checks whether the metric ordering of a pair of MT systems agrees with the human ordering. However, unlike Pearson correlation, it is not sensitive to whether the metric score differences correspond to the human score differences. We stay with Pearson correlation for the official results, but also report Kendall's Tau correlation in the appendix.

The calculation of Pearson correlation coefficient is dependent on the mean, which is very sensitive to outliers. So if we have systems whose scores are far away from the rest of the systems, the presence of these "outlier" systems can give a misleadingly high impression of the correlations, and potentially change ranking of metrics. To avoid this, we also report correlations over non-outlier systems only.

To remove outliers, we are guided by the robust outlier detection method proposed for MT metric evaluation by Mathur et al. (2020). This method, recommended by the statistics literature (Iglewicz and Hoaglin, 1993; Rousseeuw and Hubert, 2011; Leys et al., 2013) depends on the median and the median absolute deviation (MAD) which is the median of the absolute difference between each point and the median. The method removes systems whose human scores are greater than 2.5 MAD away from the median.

The cutoff of 2.5 is subjective, and Leys et al. (2013) suggest the guidelines of using 3 (very conservative), 2.5 (moderately conservative) or 2 (poorly conservative), and recommends 2.5. For some language pairs, we override the 2.5 cutoff for systems that are close to the cutoff. We give examples in Section 5, and list all identified outliers in Table 15 in the Appendix.

4.1.1 System-Level Results

Tables 5 and 6 provide the system-level correlations of metrics. These tables include results for all MT systems, and in cases where we detect outliers, we also report correlation without outliers.

This year, we also carry out an extended analysis of the impact of (multiple) human references, see the following paragraphs.

Scoring Human Translation In this section, we investigate how well the metric submissions score human translations. We have five language pairs where two reference translations were provided by WMT. The manual DA scoring of News Translation Task included all the out-of-English human references in the evaluation along with the MT systems.

Table 6: Pearson correlation of out-of-English system-level metrics with DA human assessment over MT systems using the newstest2020 references; For language pairs that contain outlier systems, we also show correlation after removing outlier systems. Correlations of metrics not significantly outperformed by any other for that language pair are highlighted in bold.

The English → Inuktitut human evaluation only contained the news subset, so we recompute en-iu system scores of metrics on the news subset of the testset (1405 sentences).

Note that the scores of parBLEU and parchrF were computed as average of segment scores

Table 7: Evaluating Human translation: Pearson correlation of metrics with DA human assessment for all MT systems plus Human translation. The subscript *B* represents an alternate reference, *P* represents a paraphrased reference. N is the total number of MT systems (excluding outliers) and HID is the identity of the human translation evaluated. Correlations of metrics not significantly outperformed by any other for that language pair are highlighted in bold.

For to-English language pairs, only the secondary human reference translations were manually scored with DA as the primary human reference translation was shown to the monolingual annotators.

For these language pairs, the metrics can score a human translation by using the other one as the reference translation. For simplicity, we add the second human reference translation to the list of translation outputs and observe how its scoring by the given metric affects the correlation.

Table 7 shows how well the metrics correlate with the WMT human evaluation when including human translations as additional output. In most cases, the correlation decreases as metrics struggle to correctly score translations that are different from MT systems. Metrics that rely on fine-tuning on existing human assessments from the previous WMT campaigns (e.g. BLEURT, ESIM, COMET) can handle human translations much better on average. Also, the Paraphrased references help the lexical metrics correctly identify the high quality of human translations.

We present a deeper analysis of how metrics score human translations in Section 5.1.2. We base this discussion on scatterplots of human vs metric scores. We include scatterplots of selected metrics in Appendix B.

Influence of References Rewarding multiple alternative translations is the primary motivation behind multiple-reference based evaluation. It is generally assumed that using multiple reference translation for automatic evaluation is helpful as we cover a wider space of possible translations (Papineni et al., 2002b; Dreyer and Marcu, 2012; Bojar et al., 2013). Nevertheless, new studies (Freitag et al., 2020) showed that multi-reference evaluation does not improve the correlation for high quality output anymore. Since we have multiple references available for five language pairs, we can look at how much the choice of reference(s) influences correlation.

Table 8 compares metric correlations on the primary reference set *newstest2020*, alternative reference *newstestB2020*, paraphrased reference *newstestP2020* (only for English-German), or using all available references *newstestM2020*. We only report system-level correlations of metrics on MT systems after discarding outliers.

4.2 Segment- and Document-Level Evaluation

Segment-level evaluation relies on the manual judgements collected in the News Translation Task evaluation. This year, again we were unable to follow the methodology outlined in Graham et al. (2015) for evaluating of segment-level metrics because the sampling of segments did not provide sufficient number of assessments of the same segment. We therefore convert pairs of DA scores for competing translations to DARR better/worse preferences as described in Section 2.3.2. We further follow the same process to generate DARR ground truth for documents, as we do not have enough annotations to obtain accurate human scores.

We measure the quality of metrics' scores against the DARR golden truth using a Kendall's Tau-like formulation, which is an adaptation of the conventional Kendall's Tau coefficient. Since we do not have a total order ranking of all translations, it is not possible to apply conventional Kendall's Tau given the current DARR human evaluation setup (Graham et al., 2015).

Our Kendall's Tau-like formulation, τ, is as follows:

$$\tau = \frac{|Concordant| - |Discordant|}{|Concordant| + |Discordant|} \quad (2)$$

where $Concordant$ is the set of all human comparisons for which a given metric suggests the same order and $Discordant$ is the set of all human comparisons for which a given metric disagrees. The formula is not specific with respect to ties, i.e. cases where the annotation says that the two outputs are equally good.

The way in which ties (both in human and metric judgement) were incorporated in computing Kendall τ has changed across the years of WMT Metrics Tasks. Here we adopt the version used in WMT17 DARR evaluation. For a detailed discussion on other options, see also Macháček and Bojar (2014).

Whether or not a given comparison of a pair of distinct translations of the same source input, s_1 and s_2, is counted as a concordant (Conc) or disconcordant (Disc) pair is defined by the following matrix:

In previous years, we used bootstrap resampling (Koehn, 2004; Graham et al., 2014) to estimate confidence intervals for our Kendall's Tau formulation, and metrics with non-overlapping 95% confidence

Table 8: Influence of references: Pearson correlation of metrics with DA human assessment for MT systems excluding outliers in WMT2020 for all language-pairs with multiple references; correlations of metrics not significantly outperformed by any other for that language pair are highlighted in bold. The subscript *B* represents a secondary reference, *P* represents a paraphrased reference, *M* represents all available references.
Note that we exclude reference-free metrics from this table, so the winners are not comparable with the main tables.

		Metric		
		$s_1 < s_2$	$s_1 = s_2$	$s_1 > s_2$
Human	$s_1 < s_2$	Conc	Disc	Disc
	$s_1 = s_2$	–	–	–
	$s_1 > s_2$	Disc	Disc	Conc

intervals are identified as having statistically significant difference in performance. The tests are inconclusive for most metric pairs this year and we do not include them in the paper.

4.2.1 Segment-Level Results

Results of the segment-level human evaluation for translations sampled from the News Translation Task are shown in Tables 9 and 10, We expect that comparing between segments translated by two MT systems that are far apart in quality would be a relatively easier task for automatic metrics. So we also include results after discarding segments that were translated by outlier systems.

Note that we do not include any human-translated segments in this evaluation.

4.3 Document-level Results

Results of the document-level human evaluation for translations sampled from the News Translation Task are shown in Tables 11 and 12.

5 Discussion

5.1 System-Level Results

In general, there is no clear best metric this year across all language pairs. For most language pairs, the William's significance test results in large clusters of metrics. The set of "winners" according to the test (i.e., the metrics that are not outperformed by any other metric) are typically not consistent across language pairs.

The sample of systems we employ to evaluate metrics is often small, as few as six MT systems for Pashto → English, for example. This can lead to inconclusive results, as identification of significant differences in correlations of metrics is unlikely at such a small sample size. Furthermore, Williams test takes into account the correlation between each pair of metrics, in addition to the correlation between the metric scores themselves, and this latter correlation increases the likelihood of a significant difference being identified. In extreme cases, the test would have low power when comparing a metric that doesn't correlate well with other metrics, resulting in this metric not being outperformed by other metrics despite having a much lower value of correlation.

To strengthen the conclusions of our evaluation, in past years (Bojar et al., 2016, 2017; Ma et al., 2018), we included significance test results for large hybrid-super-samples of systems 10K hybrid systems were created per language pair, with corresponding DA human assessment scores by sampling pairs of systems from the News Translation Task, creating hybrid systems by randomly selecting each candidate translation from one of the two selected systems. However, as WMT human annotations are collected with document context in 2020, this style of hybridization is susceptible to breaking cross-segment references in MT outputs and it would be unreasonable to shuffle individual segments. The creation of hybrid systems would need to be done by sampling documents instead of segments from all sets of systems. Finally, it is possible that including documents translated by outlier systems might falsely lead to high correlations. We believe that this merits further investigation based on data from previous of metrics tasks, and we do not attempt it this year.

In the rest of this section, we present analysis of various aspects of system-level evaluation based on scatterplots of all metrics. Appendix B contains scatterplots of metrics for each language pair. We include BLEU, chrF, the "best" reference-based metric and the "best" reference-free metric (we acknowledge that this is not the best way to define the best metric, but we choose the metric that is most highly correlated with humans on the set of all MT systems after removing outliers).

5.1.1 Influence of Domain in English → Inuktitut

English → Inuktitut training data was the Canadian Hansards domain, and the development data contained a small amount of news data. The test set was a mix of in-domain data from the Hansards and news documents. The evaluation was only done on the out-of-domain news documents, so we also look at metric scores computed only on the subset of news sentences.

Figure 1 shows that BLEU scores on the out-of-domain dataset are considerably smaller than the full dataset, showing that MT systems have a higher quality on the in-domain dataset. The relative scores of metrics remain mostly stable when we compare scores on the full test set to scores on

Table 12: Document-level metric results for out-of-English language pairs: Kendall's Tau formulation of document-level metric scores with DOC-DARR judgements. For language pairs that contain outlier systems, we also show correlation after discarding documents translated by outlier systems

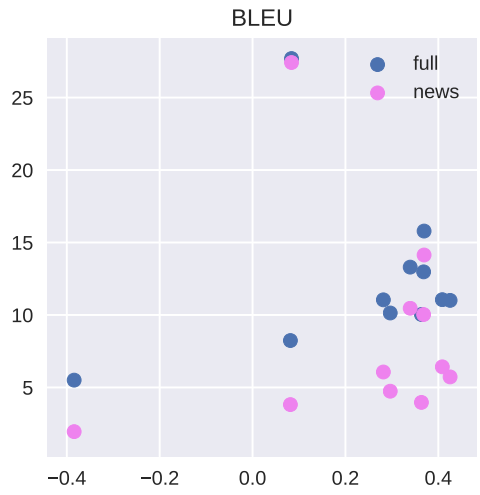

Figure 1: English → Inuktitut: Human vs. BLEU scores on the full dataset vs. the news subset. Only the news subset was included in the human evaluation. Each dot corresponds to an MT system, the outlier on the top-right is UQAM_TANLE.

only the news subset that was evaluated. The main exception is UQAM_TANLE; BLEU scores are really high on the out-of-domain data, and increase very little when computed on the full dataset. When looking at correlations with human scores (Table 7), we expected correlations to increase when computed over the news subset. This is true for most metrics such as COMET-QE, but the correlation stays the same or actually decreases for other metrics like PARBLEU.

5.1.2 Scoring Human Translations

The alternate reference was included in the manual evaluation for German → English, Russian → English and Chinese → English. All human references were included in the out-of-English manual evaluation.[7]

German → English: HUMAN-B was ranked third in the manual evaluation. The lexical metrics (BLEU, CHRF, CHARACTER, EED, MEE, YISI-0, CHRF++, PARBLEU, PARCHRF) give extremely low scores to the HUMAN-B reference. This is also true for PRISM and all the reference-free metrics except COMET-QE. The neural metrics also give low scores to the human reference, however, the margin of error is much smaller. COMET-QE is the only metric that gives high scores to the HUMAN-B reference.

Appendix B also shows the scatterplot "newstestB2020" where HUMAN-B served as the reference for the metrics. We see some differences in the vertical axis but the general picture remains the same even with this fairly different human translation.

Russian → English: The HUMAN-B reference was ranked after 6 MT systems in the manual evaluation but still within the same cluster, so not significantly distinguishable. Lexical metrics give relatively low scores to HUMAN-B. The neural metrics give relatively higher scores, but score it above *Online-A* and below *ariel197197*, i.e. differently than DA judgements.

Chinese → English: The Human translation is ranked 12th in the manual evaluation (in a giant cluster which puts together all but one top and one bottom system), and most metrics place it more or less correctly. Many metrics, including lexical metrics, still have correlations above 0.9 even after including the Human translation.

English → German: According to the WMT human evaluation, the HUMAN-B reference receives the highest scores, the HUMAN-A reference is ranked fourth and Human-P, which was generated by linguists paraphrasing the WMT references, is ranked lower at 10th place. Each human reference falls into a separate cluster of significance.

Lexical metrics score around 10 MT systems above each WMT reference (using the other WMT human translation as reference). COMET-QE and some neural metrics (BLEURT, COMET-MQM, COMET-HTER and MBERT-L2) score HUMAN-A and HUMAN-B as better than all MT systems.

When using either of the WMT references, most metrics, including all the lexical metrics, score the paraphrased reference much lower than the rest of the systems. The COMET family of metrics and BLEURT-EXTENDED are the only metrics that are able to recognise the merit of the paraphrased references.

When using the paraphrased references, all reference-based metrics score the two human translations above all MT systems, often by a large margin. PRISM is the sole exception; it scores the HUMAN-B reference about half way between the MT systems. Interestingly, most of these metrics score HUMAN-A above HUMAN-B, i.e. dis-

[7] Findings 2020 in the official tables label the alternate reference in into-English direction simply as HUMAN. The "first" reference, which serves as the primary reference for us, was not scored manually in DA into English. Out of English, the primary reference for us is labelled HUMAN-A in Findings.

agreeing with DA judgements. Metric correlations when including HUMAN-A system drop dramatically when using the alternate WMT reference, but the correlations are higher with the paraphrased reference. This also holds when scoring HUMAN-B using the paraphrased vs the main WMT reference (Table 7).

Of the reference-free metrics, COMET-QE scores the two WMT references above all MT systems, and ranks the paraphrased reference similar to its rank in the manual evaluation. OPENKIWI-BERT and OPENKIWI-XLMR are a little biased against these human translations, and YISI-2 scores all human translations below all MT systems.

English → Chinese The manual evaluation ranks the two Human translations above all MT systems, but most metrics give these much low scores.

To summarize, we see that the current MT metrics generally struggle to score human translations against machine translations reliably. Rare exceptions include primarily trained neural metrics and reference-less COMET-QE. While the metrics are not really prepared to score human translations, we find this type of test relevant as more and more language pairs are getting closer to the human translation benchmark. A general-enough metric should be thus able to score human translation comparably and not rely on some idiosyncratic properties of MT outputs. We hope that human translations will be included in WMT DA scoring in the upcoming years, too.

5.1.3 Influence of Outliers

There are no outlier systems for some language-pairs like Khmer→ English and English → Russian. For others, we have systems whose score is far away from the scores of the rest of the systems. As these outliers have a large influence on Pearson correlation, computing the correlation without outliers typically makes the task harder for metrics and results in a decrease in correlation.

For example, we identify three outliers in the German → English set; the quality of the last system is extremely low compared to rest. All reference-based metrics have high correlations when including all systems, but correlations drop when discarding outliers. In particular, CHRF and PARESIM both had a correlation of 0.95 when computed over all systems, but this drops to 0.69 and 0.83 respectively after removing outliers, revealing that PARESIM is more reliable with this language pair. An even larger drop is observed for CHRF and CHRF++ in English → Czech, from 0.8 to 0.3. We find this particularly surprising because CHRF has always performed well on this language pair, including in the evaluation on the gradually reducing set of top N systems, i.e. in harder and harder conditions, see SACREBLEU-CHRF in Appendix A.4 of Ma et al. (2019).

In some cases, metrics can be inaccurate when scoring outliers, resulting in an increased correlation when correlation is recomputed over non-outlier systems. For example, with Chinese → English, the score of WMTBIOMEDBASELINE score is much lower than the next system. Most metrics correctly rank it last as well, but COMET-HTER, COMET-MQM, COMET-QE and OPENKIWI-BERT give it a higher score than the next system(s). Note that the other metrics all have a correlation of above 0.9 even after removing the outlier.

In other cases, removing outliers decreases the correlation of a metric and yet it helps its final outcome. For instance SENTBLEU averaged over all sentences becomes one of the "winners" in the system-level evaluation of translation into English (Table 5). If we trust the results without outliers more, using *averaged sentBLEU* seems better than using plain old BLEU and not significantly worse than any other metric going from English into several target languages.

For some language-pairs, we override the decisions made by the outlier detection algorithm, based on whether we believe including or removing these systems from consideration would have an impact on the correlations: For example, with Tamil → English, the last two systems are not classified as outliers by the algorithm, but their human scores is some distance away from the rest of the systems. CHRF, CHRF++ and PARCHRF++ are the only metrics that correctly order these two systems. OPENKIWI-BERT and OPENKIWI-XLMR both get these two systems wrong with a large margin. But for all metrics, removing these systems leads to a significant drop in correlation. Thus we count these two systems as outliers.

Another example is Japanese → English. For this language-pair, we have two clusters of 7 and 3 systems. Metrics have high correlations when considering all systems, but when looking at MT

systems within individual clusters, there are discrepancies between the metric scores compared to human scores. The outlier detection algorithm flags only the last two systems as outliers, but the presence of the third system has a disproportionate impact on the correlation. We include all three systems in the set of outliers.

The influence of references For all language pairs where multiple references were available, the correlations are typically very close whether using the primary reference or the alternate reference. For metrics where we do see a difference, there is no consistent pattern whether metrics prefer one reference or the other. We note that although the change in correlations is small when comparing across reference sets, the set of "winners" according to the William's test for statistical significance is not stable, particularly for English → German. When combining references, in most cases, the correlation with multiple references lies between the correlation of the individual references. For example, with English → German, BLEU correlates best with the secondary reference with a correlation of 0.844. But with multiple references, the correlation is 0.825, just above the correlation with the primary reference with is 0.822 (Table 8).

There are a few exceptions where there is a small increase in metric correlation above both individual references. For example, the correlation of CHARACTER with German → English increases from 0.687 and 0.696 with a single reference to 0.713 with both references (Table 8). But there are no metrics which consistently show an improvement with multiple references across multiple language pairs.

5.1.4 Neural vs. Lexical Metrics

For many language pairs, when we look at correlation clustering of the reference-based metrics based on their system-level scores, we end up with two major clusters: neural metrics and lexical metrics. We have seen that lexical and neural metrics differ in how they score the human translations. For English → German, all lexical metrics have a slightly higher correlation than any neural metric when evaluating MT systems. However, these metrics make major errors evaluating the HUMAN-A translations with the HUMAN-B reference.

We also see such differences with some MT systems. Selected examples:

- English → Czech: All lexical metrics including BLEU and CHRF are very biased towards ONLINE-B, with metric scores indicating that this system is better than all others by a large margin. It is ranked 7th in the human evaluation. Neural metrics and reference-free metrics are more or less correct when scoring this system. Surprisingly, ESIM is an exception to this, and also ranks ONLINE-B on top.
- Polish → English: Lexical metrics like BLEU give very low scores to ONLINE-G.
- Tamil → English: Lexical metrics consistently score ONLINE-Z above MICROSOFT_STC_INDIA, but the remaining metrics including the reference-free metrics rank them in the opposite order. The human evaluation agrees with the lexical metrics.
- Khmer → English: lexical metrics score the best system lower than the next two, whereas most neural metrics get the order of the top systems right.

5.1.5 Other Discrepancies between Metric and Human Scores

Here we briefly draw attention to particularities we spotted when manually examining the results.

- German → English: All metrics score Tohoku-AIP-NTT higher than OPPO, and UEDIN higher than PROMT_NMT.
- Russian → English: ONLINE-A, which is ranked 2nd in the human evaluation, receives low metric scores. In contrast, some metrics including BLEU and PARBLEU choose ARIEL197197, which is ranked 6th in the human evaluation, as the best system.
- Tamil → English: The highest ranked system according to human scores, GTCOM, receives lower metric scores than the next three to six systems. Metrics are biased towards ONLINE-A and against ONLINE-Z.
- Chinese → English: HUOSHAN_TRANSLATE is a clear winner according to human evaluation, but BLEU ranks it lower than the next 3 systems. The different between human scores for the next 8 systems is not statistically significant where metric ordering of the systems differently than human scores and these discrepancies aren't penalised harshly by Pearson correlation.

- English → Chinese: HUOSHAN_TRANSLATE is a clear winner according to human evaluation, but BLEU ranks it lower than the next 3 systems. The different between human scores for the next 8 systems is not statistically significant where metric ordering of the systems differently than human scores and these discrepancies aren't penalised harshly by Pearson correlation. While many metrics including BLEU have high correlations, others make major errors scoring the NIUTRANS. OPENKIWI-BERT assigns really low scores to

Overall, we note that these metric-human discrepancies often feature online systems which are probably more diverse that the MT system submissions to the WMT shared tasks.

5.1.6 Pearson vs. Kendall Tau

Overall, we found that Pearson correlation doesn't always give us the complete picture. In particular, outliers have a large influence on the correlation and can mask the presence of discrepancies between metric and human scores with the rest of the systems. But making a decision on which systems to discard is not easy.

In this paper, we also explore Kendall's Tau as an alternative to Pearson correlation. Tables 16 and 17 in the Appendix show Kendall Tau correlation of metrics over all MT systems (not including human translations).

Kendall's Tau is less sensitive to outliers, and directly measures whether metrics agree with humans when comparing pairs of systems. However, Kendall's Tau doesn't consider the differences in scores, and two metrics whose errors differ in magnitude can have the same Kendall's Tau correlation (Figure 2).

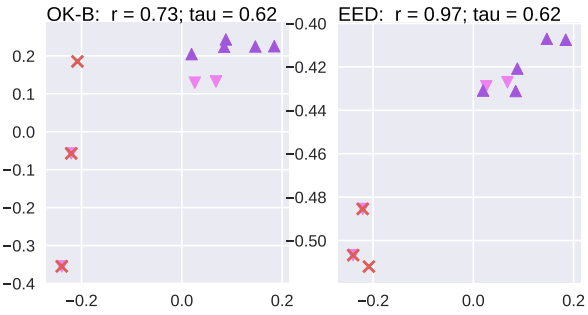

Figure 2: Scatterplots of human scores against two metrics that have the same Kendall Tau correlation with human scores, though OPENKIWI-BERT has bigger errors.

5.2 Segment and Document-Level Results

On the more fine-grained evaluation scales, PRISM and the trained neural metrics (the COMET and BLEURT family of metrics) have a better agreement with human judgements than lexical metrics

The correlations of the to-English language pairs are consistently much lower, on average, compared to that of the out-of-English language pairs. The difference could be due to the differing set of annotators: the to-English human evaluation was crowdsourced and therefore is likely to be noisier.

Finally, we find that correlations drop markedly for most language pairs if we consider only the segment/document pairs that do not contain outlier systems. We suspect that as the quality of outlier system translations is typically low, and most of the generated better-worse pairs that contain outliers can be easy for metrics. Removing these pairs would make the task a lot harder. It is also very likely that the remaining pairs of translations are noisier, which decreases metric agreement with these pairwise judgements.

The document-level correlations are typically higher than segment-level correlations. This could be due to reduced noise in human scores when averaging the scores of multiple segments. Computing metric scores over documents that contain multiple segments also helps reduce metric noise.

5.3 Reference-Based Metrics vs. Reference-Free Metrics

We have four submissions of metrics that directly compare MT outputs with the source segment: COMET-QE, OPENKIWI-BERT, OPENKIWI-XLMR, and YISI-2. Other members of the COMET family of metrics use information from both the source and reference. The remaining metrics compute scores by comparing the MT output with the reference.

While the task of comparing segments in different languages is harder than comparing segments in the same language, reference-free metrics have one advantage: they are not encumbered by reference-bias. COMET-QE is the only metric that correctly gives a high score to the human translation in German → English , and one of the few metrics that does so for English → Chinese.

This year, the reference-free metrics are highly competitive with reference-based metrics for all language-pairs. For English → Tamil, COMET-

QE which has a near perfect correlation of 0.97 even after discarding outliers. In contrast, many reference-based metrics including BLEU and chrF give really high scores to ONLINE-B, which results in low correlations.

6 Use Automatic Metrics to Detect Incorrect Human Preference

It has been argued that non-expert translators lack knowledge of translation and so might not notice subtle differences that make one translation better than another. Castilho et al. (2017) compared the evaluation of MT output of professional translators against crowd workers. Results showed that for all language pairs, the crowd workers tend to be more accepting of the MT output by giving higher fluency and adequacy scores. Toral et al. (2018) showed that the ratings acquired by professional translators show a wider gap between human and machine translations compared to judgments by non-experts. They recommend using professional linguists for MT evaluation going forward. Läubli et al. (2020) show that non-experts assess parity between human and machine translation where professional translators do not, indicating that the former neglect more subtle differences between different translation outputs. Given the previous work and the fact that the WMT human evaluation has been conducted with a mix of researchers and crowd workers, we rerun human evaluation for a subset of the submissions with professional linguists. In particular, we want to investigate if we can use the quality scores obtained by the automatic metrics to detect incorrect human ratings. We filtered out all pairs of systems where the human evaluation results disagree with all automatic metrics. Taking the metric scores as a signal, we rerun human evaluation for a subset of submissions for 2 language pairs: German→English and English→German. We hired 10 professional linguists, who rerun the source-based direct assessment human evaluation with the same document-based template that has been used for the original WMT ratings.

6.1 German→English

For German→English, we found that all automatic metrics disagree with the human evaluation results for OPPO and TOHOKU. OPPO yields a higher human rating, while all automatic metrics gave TOHOKU a higher score. To investigate which of the results to trust, we rerun the source-based direct assessment for these 2 systems with professional linguists. The results in Table 13 show that professional linguists in fact prefer the output of TOHOKU as predicted by all automatic metrics.

Evaluation	OPPO	TOHOKU
avg metric (HUMAN-A ref)	8.85	**8.95**
avg metric (Human-B ref)	10.15	**10.26**
WMT	**84.6**	81.5
z-score	**0.220**	0.179
prof. linguist	81.0	**81.7**
z-score	-0.005	**0.010**

Table 13: WMT 2020 German→English comparing the reference-based ratings acquired with crowd workers/researcher (WMT) against source-based ratings acquired with professional linguists.

6.2 English→German

For English→German, we rerun human evaluation for the top 2 ranked MT systems (based on human evaluation): OPPO, TOHOKU and the human translation HUMAN-A. The quality of human translations is usually underestimated by automatic metrics when computed with standard references. This is also visible in this year's evaluation campaign where the average metric scores of all submission for the human translation HUMAN-A is much lower when compared to the top MT submissions. To overcome this problem, Freitag et al. (2020) introduced paraphrased references that also value the translation quality of human translations and alternative (less simple/monotonic) MT output. As we can see in Table 14, the average metric scores of all submissions when computed with the paraphrased references HUMAN-P yield a much higher score for the human translation HUMAN-A when compared to all MT outputs.

The official WMT human evaluation ranked the human translation third, right behind the two MT outputs from OPPO and TOHOKU. Interestingly, based on the z-scores, WMT predicts OPPO to be of higher quality than TOHOKU which is in disagreement with most of the metric scores when calculated against both types of reference translations. Overall, the automatic metrics come to a very different ranking than the human evaluation for the top performing submissions.

Evaluation	OPPO	TOHOKU	HUMAN-A
avg metric (Human-B ref)	10.05	**10.09**	9.14
avg metric (Human-P ref)	11.93	12.07	**15.74**
WMT	87.39	**88.62**	85.10
z-score	**0.495**	0.468	0.379
prof. linguist	73.66	74.70	**84.09**
z-score	-0.051	-0.037	**0.088**

Table 14: WMT 2020 English→German comparing the source-based ratings acquired with crowd workers/researcher (WMT) against source-based ratings acquired with professional linguists.

We rerun the human evaluation with the same template, but with professional linguists. Interestingly, the human translation has been ranked first by a large margin. Furthermore, the MT output of TOHOKU has been rated as higher quality when compared to the MT output from OPPO. The results of the human evaluation with professional linguists yield a perfect correlation to the metric scores calculated with the paraphrased reference. This indicates not only the advantages of paraphrased references when scoring human translations, but also that automatic metrics can be used to identify incorrect human ratings.

7 Conclusion

This paper summarizes the results of WMT20 shared task in machine translation evaluation, the Metrics Shared Task. Participating metrics were evaluated in terms of their correlation with human judgement at the level of the whole test set (system-level evaluation), as well as at a more fine-grained level (document-level evaluation and sentences or paragraphs for segment-level evaluation). We reported scores for standard metrics requiring the reference as well metrics that compare MT output directly with the source text. For system-level, best metrics reach over 0.95 Pearson correlation or better across several language pairs. In many cases, this correlation drops considerably when the correlation is recomputed after discarding outlier systems.

Computing Pearson correlation without outliers can change the rankings of metrics, and selecting these outlier systems is not an exact science. We report results both with all systems and after discarding outliers as together, and also include Kendall Tau correlation, and hope that together, they give a more complete picture than just reporting only one of these numbers. In the end, we believe that it is impossible to adequately describe data with summary numbers, and that it's best to visualise data to understand patterns.

The results confirm the trends from previous years, namely metrics based on word or sentence-level embeddings, achieve the highest performance (Ma et al., 2018, 2019).

For some language pairs, we had two references available. On these test sets, we found that computing scores with two references rarely helped metrics achieve a higher correlation than using either reference individually. This contradicts earlier research that shows that multiple references improve correlation (Bojar et al., 2013), but is in line with more recent papers that show additional independent references might not be helpful (Freitag et al., 2020). We believe that the utility of additional independent references is dependent on the MT systems evaluated, that perhaps they are not as helpful when scoring high quality MT systems as with low/mid quality MT.

In addition to scoring MT systems, this year, we also requested scores for human reference translations. This highlighted the difference between lexical and embedding-based metrics, as lexical metrics consistently gave low scores to human translations. However, when using the English-German paraphrased references, all metrics scored the other human references above all MT systems, highlighting the advantages of using paraphrased references when scoring human translations.

In addition to human references, there are some MT systems where metrics (either the majority of metrics, or only the lexical metrics) make major errors. It remains an open question as to what it is about these systems that metrics struggle with scoring them correctly.

Compared to last year, the performance of the reference-free metrics has improved, and the correlations this year are competitive with the reference-based metrics, and in many cases, outperform BLEU. In particular, COMET-QE is good at recognising the high quality of human translations where BLEU falls short.

In terms of segment-level Kendall's τ results, the standard metrics correlations was very low for the to-English language pairs, particularly after discarding translations by outlier systems. The corre-

lations of the out-of-English language pair are more in line with recent years, reaching a maximum of above 0.6.

It has been shown that context is really important when humans are rating MT outputs (Toral et al., 2018), and the WMT human evaluation is moving towards evaluating segments with the document context (Barrault et al., 2019). This creates a mismatch with automatic metrics, all of which, this year, score each segment independently. This year, we introduce document-level evaluation of metrics. When computing document-level scores, some metrics from the COMET family include document context when computing segment scores within the document. All other metrics included in this year's evaluation either use the average of the segment scores or compute the document score based on statistics computed independently for each segment. In the future, we hope to see more metrics that consider broader context when evaluating translations at all three levels.

For this year, we are unable to draw any meaningful conclusions from the document-level evaluation task, as it is hard to tease apart the influence of noise in the ground truth, inadequate segment-level translations and inadequate translation in context of the document.

We believe that the noise in the DARR judgements is a big factor in the low correlations in the to-English language pairs. We need further research into understanding the factors that contribute to the Kendall Tau scores and how much we can trust these results.

There are shortcomings in the methods used to evaluate metrics at the system-, document-, and segment-level, and we believe that improving methods for evaluating and analysing automatic metrics is a rich area for future research.

Finally, we assume that any discrepancies between metrics and WMT manual evaluation is a metric error, and we acknowledge that this might not be true in all cases. There is always scope for improvement in human evaluation methodology, and the best practice recommendations for human evaluation are always evolving.

We rerun human evaluation by using the same template as the WMT evaluation, but switching the rater pool from non-experts to professional linguists for a subset of translations where all metrics disagree with the WMT human evaluation. This experiment revealed a new use case of automatic metrics and demonstrated that automatic metrics can be used to identify bad ratings in human evaluations. The new obtained ratings were in line with the scores suggested by the automatic metrics and also confirmed the higher translation quality of human translations when compared to MT output.

In this paper, we looked at how outliers influence metric evaluation, and we wonder how the presence of these systems influence DA annotations. In a perfect world, annotators score each translation on its own merits without being influenced by previous instances. In this world, given the presence of much worse translations, do annotators assign high scores to the remaining translations that look relatively better? Does an MT system receive an unfair advantage if it is consistently scored alongside a low-scoring outlier? And does standardising the scores of individual annotators exacerbate this issue? These and other research questions remain open this year, keeping the WMT tasks increasingly interesting as MT systems are getting closer to human performance.

Acknowledgments

Results in this shared task would not be possible without tight collaboration with organizers of the WMT News Translation Task.

We are grateful to Google for sponsoring the evaluation of selected MT systems by professional linguists. We thank all participants of the task, particularly Weiyu Wang for pointing out some inconsistencies with the original release of inputs, Jackie Lo, Ricardo Rei, and Craig Stewart for some helpful feedback and Thibault Sellam for also submitting the scores of finetuned BERT on our request.

Table 15: List of all MT systems that we consider as outliers

B Scatterplots

Here we show scatterplots of human and metric scores of selected metrics.

We report the correlation of each metric with human scores on all systems as well as all systems minus the outliers. Note that we do not exclude human translations when computing these correlations.

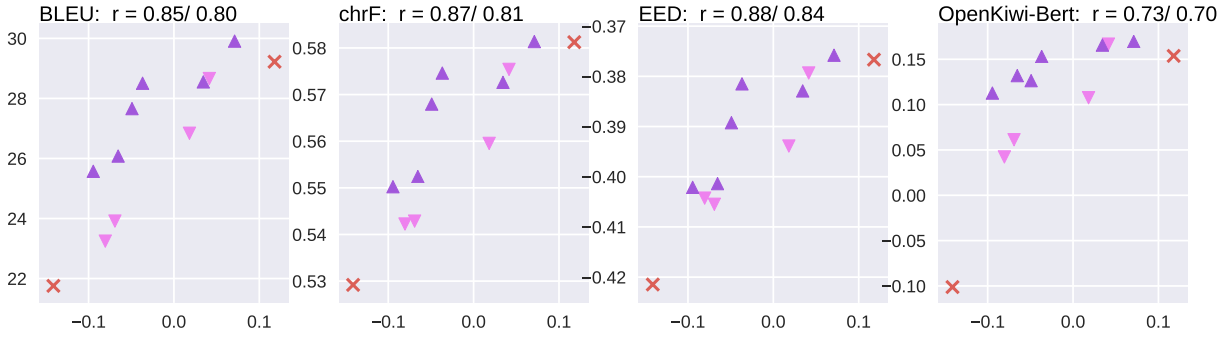
In the following scatterplots, the violet triangles indicate individual indicate MT system submissions by researchers and pink downward triangles are online systems. [8] The red crosses are outlier systems.

The black diamonds are human translations. For newstest2020 reference set, this is the HUMAN-A translation, and for newstestB2020 reference set, this is the HUMAN-B translation. The plots for English → German have two human translations included, and we annotate the label in the plot. In many cases, metric errors scoring these translations stand out.

Metric scores of MT systems with multiple references does not deviate from the scores of either reference. So we do not include the scatterplots of the other reference sets unless a human translation is included (which is interesting).

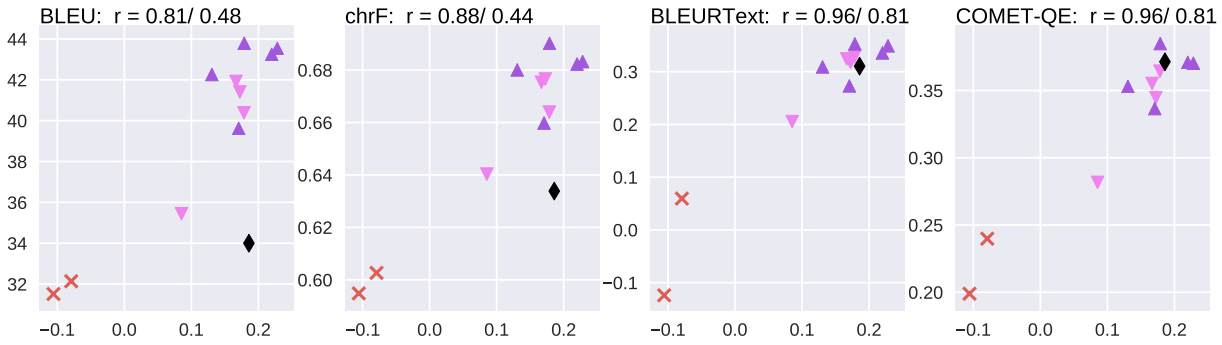
We will have scatterplots for all metrics over all reference sets in the metrics package to be made available at http://www.statmt.org/wmt20/results.html

cs-en



[8] We distinguish between the two in these scatterplots as we notice that metrics often make errors when scoring online systems.

de-en newstest2020[a]



[a]Including the YOLO.1052 system, which has an extremely low quality, would make it hard to distinguish between the rest of the systems, so these plots exclude the system.

Abstract

Following two preceding WMT Shared Tasks on Parallel Corpus Filtering (Koehn et al., 2018, 2019), we posed again the challenge of assigning sentence-level quality scores for very noisy corpora of sentence pairs crawled from the web, with the goal of sub-selecting the highest-quality data to be used to train machine translation systems. This year, the task tackled the low resource condition of Pashto–English and Khmer–English and also included the challenge of sentence alignment from document pairs. 10 participants from companies, national research labs, and universities participated in this task.

1 Introduction

The field of Machine Translation has experienced significant advances in recent years thanks to improvements in neural modeling (Bahdanau et al., 2015; Gehring et al., 2016; Vaswani et al., 2017), as well as the availability of large parallel corpora for training (Tiedemann, 2012; Smith et al., 2013; Bojar et al., 2017). Unfortunately, today's neural machine translation models, perform poorly on *low-resource* language pairs, for which clean, high-quality training data is lacking (Koehn and Knowles, 2017). Improving performance on low resource language pairs has high impact considering that these languages are spoken by a large fraction of the world population. This is a particular challenge for industrial machine translation systems that need to support hundreds of languages in order to provide adequate services to their multilingual user base.

While there have been advances in using monolingual corpora (Lample et al., 2018; Liu et al., 2020) and parallel corpora in multiple language pairs (Aharoni et al., 2019; Fan et al., 2020), the best training data for machine translation are still parallel corpora in the targeted language pair and domain.

Parallel corpora are typically gathered from any available source without much guarantees about quality. This is especially the case for parallel corpora that are extracted from the web without much control over which web sites are mined. Since noisy training data has been recognized as a challenge for neural machine translation training (Khayrallah and Koehn, 2018), an essential step in using such data is filtering or discounting noisy sentence pairs.

Recently, there is increased interest in the filtering of noisy parallel corpora to improve the data that can be used to train translation systems. The Shared Task on Parallel Corpus Filtering and Alignment at the Conference for Machine Translation (WMT 2020) was organized to promote research to make learning from noisy data more viable for low-resource languages. It is similar to the previous year's task but tackles different languages (Pashto and Khmer instead of Nepali and Sinhala) and also included the challenge to extract sentence pairs from document pairs.

The shared task is organized similarly to previous years (Koehn et al., 2018, 2019). We provide about 11.6 million word noisy parallel data for Pashto-English and 58.3 million word noisy parallel data for Khmer-English. We also provide small amounts of clean parallel data of varying quality and monolingual data from Wikipedia and CommonCrawl.

Participants developed methods to assign a quality score for each sentence pair. These scores are used to filter the web crawled corpora down to

Proceedings of the 5th Conference on Machine Translation (WMT), pages 726–742

a fixed size (5 million English words), train neural machine translation systems on these subsets, and measure their quality with the BLEU score on a test set of multi-domain Wikipedia content (Guzmán et al., 2019).

This paper gives an overview of the task, presents the results for the participating systems and provides analysis on additional subset sizes, the average sentence length of sub-selected data, and overlap between the submissions.

2 Related Work

Although the idea of crawling the web indiscriminately for parallel data goes back to the 20th century (Resnik, 1999), work in the academic community on extraction of parallel corpora from the web has so far mostly focused on large stashes of multilingual content in homogeneous form, such as the Canadian Hansards, Europarl (Koehn, 2005), the United Nations (Rafalovitch and Dale, 2009; Ziemski et al., 2015), or European Patents (Täger, 2011). A nice collection of the products of these efforts is the OPUS web site[1] (Tiedemann, 2012).

2.1 Parallel Corpus Acquisition

Noisy parallel documents and parallel sentences were sourced from the CCAligned[2] dataset (El-Kishky et al., 2020a), a massive collection of cross-lingual web documents covering over 8k language pairs aligned from 68 Common Crawl snapshots. Additional parallel data was sourced from the Paracrawl project – a large-scale effort to crawl text from the web[3] (Bañón et al., 2020).

Acquiring parallel corpora from the web (El-Kishky et al., 2020b) is an active area of research that typically involves identifying web sites with parallel text, downloading the documents from the web site, aligning document pairs (Buck and Koehn, 2016; Thompson and Koehn, 2020; El-Kishky and Guzmán, 2020), and aligning sentence pairs. A final stage of the processing pipeline filters out non-parallel sentence pairs. Such noise exists either because the original web site did not have any actual parallel data (garbage in, garbage out), only partially-parallel data, or due to failures of processing steps.

[3] http://www.paracrawl.eu/

2.2 Sentence Alignment

Sentence alignment has been a very active field of research since the early days of statistical machine translation. An influential early method is based on sentence length, measured in words (Gale and Church, 1993). Several researchers proposed including lexical information (Chen, 1993; Moore, 2002) with the emergence of tools that use provided bilingual dictionaries (Varga et al., 2005) or acquire them during in an unsupervised fashion (Braune and Fraser, 2010). Later work introduced scoring methods that use MT to get both documents into the same language (Sennrich and Volk, 2010) or use pruned phrase tables from a statistical MT system (Gomes and Pereira Lopes, 2016). Both methods anchor high-probability 1–1 alignments in the search space and then fill in and refine alignments. More recently, Thompson and Koehn (2019) introduced the use of sentence embeddings and a coarse-to-fine search method to the task (Vecalign).

2.3 Filtering Noisy Parallel Corpora

In 2016, a shared task on sentence pair filtering[4] was organized, albeit in the context of cleaning translation memories which tend to be cleaner than the data at the end of a pipeline that starts with web crawls.

There is a robust body of work on filtering out noise in parallel data. For example: Taghipour et al. (2011) use an outlier detection algorithm to filter a parallel corpus; Xu and Koehn (2017) generate synthetic noisy data (inadequate and non-fluent translations) and use this data to train a classifier to identify good sentence pairs from a noisy corpus; and Cui et al. (2013) use a graph-based random walk algorithm and extract phrase pair scores to weight the phrase translation probabilities to bias towards more trustworthy ones.

Most of this work was done in the context of statistical machine translation, but more recent work targets neural models. Carpuat et al. (2017) focus on identifying semantic differences in translation pairs using cross-lingual textual entailment and additional length-based features, and demonstrate that removing such sentences improves neural machine translation performance.

As Rarrick et al. (2011) point out, one type of noise in parallel corpora extracted from the web

[4] NLP4TM 2016: Shared task http://rgcl.wlv.ac.uk/nlp4tm2016/shared-task/

are translations that have been created by machine translation. Venugopal et al. (2011) propose a method to watermark the output of machine translation systems to aid this distinction, with a negligible loss of quality. Antonova and Misyurev (2011) report that rule-based machine translation output can be detected due to certain word choices, and statistical machine translation output can be detected due to lack of reordering. It is notable that none of the participants in our shared task have tried to detect machine translation.

There is a rich literature on data selection which aims at sub-sampling parallel data relevant for a task-specific machine translation system (Axelrod et al., 2011). Van der Wees et al. (2017) find that the existing data selection methods developed for statistical machine translation are less effective for neural machine translation. This is different from our goals of handling noise since those methods tend to discard perfectly fine sentence pairs that are just not relevant for the targeted domain. Our task is focused on data quality that is relevant for all domains.

2.4 Impact of Noise on Neural Machine Translation

Belinkov and Bisk (2017) investigate the impact of noise on neural machine translation. They focus on creating systems that can *translate* the kinds of orthographic errors (typos, misspellings, etc.) that humans can comprehend. In contrast, Khayrallah and Koehn (2018) examine noisy *training* data and focus on types of noise occurring in web-crawled corpora. They carried out a study about how noise that occurs in crawled parallel text impacts statistical and neural machine translation.

Neural machine translation model training may combine data selection and model training, taking advantage of the increasing quality of the model to better detect noisy data or to increasingly focus on cleaner parts of the data (Wang et al., 2018; Kumar et al., 2019).

2.5 Findings of Previous Shared Tasks

We organized versions of this shared task in the previous two years. In 2018, we started with a high-resource language pair (German–English) and a very large web-crawled parallel corpus, a subset of the Paracrawl corpus consisting of 1 billion English words (Koehn et al., 2018). The best-performing submission (Junczys-Dowmunt, 2018) used neural machine translation systems in both translation directions to score sentence pairs with dual cross-entropy.

Last year, we moved the focus to low resource languages (Koehn et al., 2019) with smaller noisy parallel corpora, comprising 50-60 million words for Nepali–English and Sinhala–English. For these languages much less clean parallel data was available and hence many of the methods developed for high-resource languages are less reliable. The best-performing submission that year (Chaudhary et al., 2019) also considered dual cross-entropy but found that matching multilingual sentence embeddings (Schwenk, 2018) gave better results.

2.6 Monolingual Pre-Training

By now, neural machine translation systems are rarely trained only on the parallel corpus of the desired language pair. Common foundations are pre-trained models trained on multiple language pairs which share the source or target language (Aharoni et al., 2019; Fan et al., 2020) or monolingual pre-training methods (Liu et al., 2020). Often, the models are also improved by a second stage of training that uses back-translated synthetic parallel data that was generated from first stage model — a process that may be iterated (Hoang et al., 2018).

To reflect such a more realistic training setup, we provided pre-trained models that were trained on monolingual data using a denoising auto-encoder method called mBART (Liu et al., 2020). Here, monolingual data is converted into input and output pairs by (a) masking out words in the input, forcing the model to learn the correct word or word sequence from the context, and (b) shuffling the order of a few concatenated sentence pairs.

3 Shared Task Definition

The shared task tackled the problem of filtering parallel corpora. Given a noisy parallel corpus (crawled from the web), participants developed methods to align sentences in document pairs and to filter it to a smaller size of high quality sentence pairs.

3.1 Filtering

For the filtering-only task, we provided a very noisy 58.3 million word corpus for Khmer–English (English token count) and a 11.6 million word corpus for Pashto–English, crawled from the

web (see Section 4.3 for details). We asked participants to generate sentence-level quality scores that allow selecting subsets of sentence pairs that amount to 5 million words, counted on the English side. This amount was chosen based on preliminary experiments (we report below on additional subset sizes).

Participants in the shared task submitted a file with quality scores, one score per line, corresponding to the sentence pairs. Scores are only required to have the property that higher scores indicate better quality. The scores were uploaded to a Google Drive folder which remains publicly accessible.[5]

3.2 Alignment

We also released the document pairs from which we extracted the sentence pairs. For Khmer–English, we released 391,250 document pairs, for Pashto-English 45,312 document pairs.

Participants were encouraged to develop novel methods for sentence alignment. The resulting sentence pairs also had to be annotated with quality scores, as in the filtering-only tasks, and uploaded with quality scores to the same Google Drive folder.

3.3 Evaluation

The submissions were scored by building a neural machine translation system (Ott et al., 2019) trained on this data, and then measuring their BLEU score on the `flores` Wikipedia test sets (Guzmán et al., 2019). The neural machine translation model was either randomly initialized or initialized by monolingual pre-training (mBART).

For development purposes, we released configuration files and scripts that mirror the official testing procedure with a development test set. The development pack consists of:

- A script to subsample corpora based on quality scores.
- `fairseq` scripts to train and test a neural machine translation system.
- A pre-trained mBART model for continued training.
- The `flores-dev` set of Wikipedia translations as development set.
- The `flores-devtest` set of Wikipedia translations as development test set.

Bible	13,432	298,522
TED Talks	664	11,157
Wikimedia	737	37,566

Table 1: Provided clean parallel data for Pashto–English.

The web site for the shared task[6] provided detailed instructions on how to use these tools to replicate the official testing environment.

4 Data

We provided three types of data for this shared task: (1) clean parallel and monolingual data, including related language data in Hindi, to train models that aid with the filtering task, (2) the noisy parallel data crawled from the web which participants have to score for filtering, and (3) development and test sets that are used to evaluate translation systems trained on filtered data.

4.1 Clean Parallel Data

For Pashto (see Table 1 for detailed statistics), the largest data sets are the Bible (prepared for us by Arya McCarthy and David Yarowsky), various data sets from OPUS[7] (GNOME, KDE4, and Unbuntu software localization; Tatoeba volunteer translations; and Wikimedia), and a TED Talks corpus created for this task, crawled from TED web site, and sentence-aligned with Vecalign (Thompson and Koehn, 2019).

For Khmer (see Table 2 for detailed statistics), the largest data sets are the alignment of 2 English with 4 Khmer Bibles, various data sets from OPUS (GNOME, KDE4, and Ubuntu software localization; GlobalVoices citizen journalism articles; Tatoeba volunteer translations; and Wikimedia). We also re-aligned the Jehova's Witness corpus (JW300), a collection of religious texts, with Vecalign.

[6] http://www.statmt.org/wmt20/parallel-corpus-filtering.html

[7] http://opus.nlpl.eu/

Corpus	Sentence Pairs	English Words
GNOME	56	233
GlobalVoices	793	14,294
KDE4	120,087	767,919
Tatoeba	748	3,491
Ubuntu	6,987	27,413

JW300	107,156	1,827,348

Table 2: Provided clean parallel data for Khmer–English.

	Wikipedia	CommonCrawl
Pashto	76,557	6,558,180
Khmer	132,666	13,832,947
English	67,796,935	1,806,450,728

Table 3: Provided clean monolingual data (number of sentences).

For both language pairs, the available clean parallel data is rather small and mostly out-of-domain. It is not sufficient to build reasonable machine translation systems. In fact, even the provided raw unfiltered noisy parallel data gives better results when used directly for training.

4.2 Clean Monolingual Data

Monolingual data is always available in much larger quantities, and we provided data from two sources: Wikipedia and CommonCrawl. Both contain language that is similar to what is expected in the noisy web data to be filtered.

We filtered the data to eliminate overlap with the development and test sets. See Table 3 for detailed statistics.

4.3 Noisy Parallel Data

Noisy parallel data sourced from CCAligned and Paracrawl follow different philosophies. While CCAligned mines bitexts from a high-precision set of aligned web-documents yielding cleaner parallel bitexts, the noisy parallel corpora from Paracrawl are the outcome of a processing pipeline aimed at high recall at the cost of precision, yielding noisy bitexts. They exhibit noise of all kinds: wrong language in source and target, sentence pairs that are not translations of each other, bad language (incoherent mix of words and non-words), incomplete or bad translations, etc.

To ensure that CCAligned yields additional noisy pairs, we don't perform any filtering after mining bitexts from the CCAligned corpus.

We used the processing pipeline of the Paracrawl project to create the data, using the clean parallel data to train underlying models such as the dictionary used by Hunalign (Varga et al., 2007) and a statistical translation model used by the document aligner. The provided parallel corpus is the raw output of the crawling pipeline, with sentence pairs de-duplicated but otherwise no further filtering performed. See Table 4 for statistics of the corpus and Tables 5 and 6 for some example sentences.

4.4 Development and Test Sets

For test and development purposes, we use the `flores` Wikipedia data sets (Guzmán et al., 2019). These sets are multi-domain, that is they were sampled from Wikipedia documents with a diverse set of topics. In Table 7 we present the statistics of these sets. The official scoring of machine translation systems generated from the sub-sampled data sources is done on the *test* set.

5 Evaluation Protocol

The testing setup mirrors the development environment that we provided to the participants.

5.1 Participants

We received submissions from 10 different organizations, and an additional baseline LASER submission that was posted on the website. See Table 8 for the complete list of participants. The participant's organizations are quite diverse, with 3 participants from the United States, 2 participants from China, and 1 participant each from Canada, Egypt, Turkey/China, Scotland, and Spain. 3 of the participants are universities, 4 are companies, 1 is a joint company/university participant, and 2 are national research organizations. There was little participant overlap between this year's shared task and last year's shared task. Only AFRL and NRC participated also last year.

Each participant submitted up to 3 different sets of scores, not all participants addressed both languages, resulting in a total of 16 different submissions for Pashto and 11 different submissions for Khmer, including a baseline submission of using

	Sentence Pairs	English Words	Document Pairs
Pashto–English	1,022,883	11,551,009	45,312
Khmer–English	4,169,574	58,347,212	391,250

Table 4: Noisy parallel data to be filtered (de-duplicated raw output). Data is made available as aligned sentence pairs (see table for number of English words) and as document pairs for which sentence alignment has to be performed.

just the LASER scores that was provided to participants at the outset.

5.2 Methods used by Participants

This year, participants in general used a broader range of features and more sophisticated classifier approaches than previously. We first provide an overview of methods and then give a short summary of each submission.

5.2.1 Methods

Pre-filtering Almost all participants employ pre-filtering rules, based on the length of sentences in terms of tokens or characters, ratio of the lengths, ratio of alpha-numerical tokens, overlap between the English and the foreign sentence (to

avoid copy noise), or mismatched email addresses, URLs or numbers.

A common pre-filtering method is also language ID. However mixed results were reported and some participants decided to not use it for Pashto (Açarçiçek et al., 2020).

Some participants worked on morphological segmentation of Khmer but this did not lead to any improvements (Esplà-Gomis et al., 2020; Koerner and Koehn, 2020).

LASER We provided LASER scores that performed well in previous year's filtering task. LASER sentence embeddings are trained as a bottleneck feature for a neural machine translation model and trained on a large collection of parallel corpora in 93 languages[8] which include Khmer but not Pashto. A similarity score for a sentence pair is computed as the cosine distance between the English sentence embedding and the foreign sentence embedding (Nokrashy et al., 2020; Kejriwal and Koehn, 2020; Koerner and Koehn, 2020).

[8] https://github.com/facebookresearch/LASER#supported-languages

Dual cross entropy Neural machine translation systems trained on the provided clean parallel data can be used by feeding in the English sentence and computing the probability of the foreign sentence according to the model, and vice versa. Junczys-Dowmunt (2018) proposed a metric that uses not only the individual computed cross entropy scores but also the difference between them (Lu et al., 2020; Koerner and Koehn, 2020).

Language models To assess the quality of sentences by themselves, i.e., preferring sentences that are fluent in the language, statistical or neural language models are trained, typically using provided Wikipedia and CommonCrawl corpora (Lu et al., 2020; Esplà-Gomis et al., 2020; Kejriwal and Koehn, 2020; Koerner and Koehn, 2020; Lo and Joanis, 2020).

Statistical word translation scores Words in the two sentences should be translation of each other. To what degree this is the case can be assessed with classic word translation models which are learned with the EM algorithm over the clean parallel data (Lu et al., 2020; Lo and Joanis, 2020; Esplà-Gomis et al., 2020).

Classifier An increasing number of participants framed the quality estimation problem as a classification task. This requires positive examples drawn from the provided clean parallel text and negative examples created by corrupting these examples. Typically this involves mismatched sentences, truncated sentences, sentences with swapped word order (Esplà-Gomis et al., 2020; Açarçiçek et al., 2020; Nokrashy et al., 2020; Xu et al., 2020). To create harder negative examples for the classifier, a sentence is paired not with a random sentence from the foreign corpus but with a neighboring sentence of the correctly paired sentence and sentences that have 60% similarity (measured by fuzzy match score) to the correct translation (Açarçiçek et al., 2020).

5.2.2 Individual Submissions

AFRL use their corpus-building method (Erdmann and Gwinnup, 2019) but with a bidirectional quality metric that nearly eliminates pre-filtering (used only for the limit on training line length). The coverage metric encourages the addition of a sentence that improves corpus-level bilingual vocabulary frequencies. The new quality metric is the average of sentence-level NMT scores ("log-likelihoods") in both directions.

Alibaba (Lu et al., 2020) use a number of features that are combined linearly: a bilingual GPT-2 model trained on source-target language pairs as well as monolingual GPT-2 model each of the languages, dual cross entropy from neural machine translation models trained in both directions and statistical word translation model scores. They report that they experimented with classifiers to weight features but found this to be not beneficial.

Bytedance (Xu et al., 2020) tackle only the combined alignment/filtering task. The sentence alignment methods draws on statistical lexical translation scores, as used in YiSi-2. They iteratively improve the lexical model by adding high-quality mined sentence pair to its training data. Their filtering method is a classifier based on monolingual language models and a cross-lingual language model (XLM), followed by an added convolutional layer. They also use language ID and n-gram coverage during a re-ranking stage and ensemble model variations (different architectures, hyper parameters).

Huawei (Açarçiçek et al., 2020) focus on an end-to-end classifier approach that learns to distinguish clean parallel data from misaligned sentence pairs. The model first uses a Transformer model to obtain sentence representations, followed either by a classifier (Siamese network) or additional layers that are fine-tuned. They report better performance with a RoBERTa-style Transformer setup over a BERT-style Transformer. A relatively small training corpus is used (2,000 or 10,000 sentence pairs) with 10x over-sampled negatives.

JHU-Kejriwal (Kejriwal and Koehn, 2020) use LASER scores with some novel transformation of score ranges, language ID confidence scores, monolingual language models trained on words and characters, and length-based filters.

JHU-Koerner (Koerner and Koehn, 2020) employ a linear combination of LASER scores, monolingual language model scores, dual cross entropy, and use a sentence duplication penalty.

Microsoft (Nokrashy et al., 2020) focus on the LASER scores, using both the provided LASER scores, custom LASER scores using a model trained on the provided clean parallel data (which are better for Pashto but worse for Khmer), and a classifier built on a pair of LASER sentence embeddings trained to distinguish between clean sentence pairs and artificially bad sentence pairs. While these three scores fare differently for the two languages pairs, a combination of them performs best.

NRC (Lo and Joanis, 2020) tackle both filtering and alignment. Their filtering score is mainly based on Yisi-2 (Lo, 2019), a language model trained on the target side, and representations obtained with XLM-RoBERTa (Conneau et al., 2020) pre-trained for Pashto, Khmer, and English. Sentence alignment is based on the approach by Moore (2002), first applied to align paragraphs and then sentences.

UA-Prompsit (Esplà-Gomis et al., 2020) use an extended version of the established Bicleaner tool which is a classifier that uses several features ranging from coarse (e.g., statistical word translation models scores) to shallow (e.g., average token length, length ratio, punctuation count). The classifier uses the extremely randomized tree algorithm. They also use a 7-gram character language model as refinement.

LASER scores were provided to participants, with filtering for language ID and maximum 60% overlap between source and target sentence.

Edinburgh did not submit a system description paper.

5.3 Subset Selection

We provided to the participants a file containing one sentence pair per line (see Section 4.3) each for the two languages. A submission to the shared task consists of a file with the same number of lines, with one score per line corresponding to the quality of the corresponding sentence pair.

To evaluate a submitted score file, we selected subsets of a predefined size, defined by the number of English words (5 million). We chose the number of English words instead of Pashto or Khmer words, since the latter would allow selection of sentence pairs with very few non-English words and many English words which are beneficial for decoder training but do not count much towards the non-English word total.

Selecting a subset of sentence pairs is done by finding a threshold score, so that the sentence pairs that will be included in the subset have a quality score at and above this threshold. In some cases, a submission assigned this threshold score to a large number of sentence pairs. Including all of them would yield too large a subset, excluding them yields too small a subset. Hence, we randomly included some of the sentence pairs with the exact threshold score to get the desired size in this case.

5.4 Evaluation System Training

Given a selected subset of a given size for a system submission, we built neural machine translation systems from scratch (SCRATCH) and by continued training on a pre-trained model (MBART) to evaluate the quality of the selected sentence pairs.

SCRATCH For from-scratch training, we used the `fairseq` (Ott et al., 2019) transformer model with the parameter settings shown in Figure 1. Preprocessing was done with sentence piece for a 5000 subword vocabulary on tokenized text using the Moses tokenizer (but no truecasing was used). Decoding was done with beam size 5 and length normalization 1.2. Training a system for the 5 million subsets took about 13 hours, on a single GTX 1080ti GPU. Scores on the test sets were computed with Sacrebleu (Post, 2018). We report case-insensitive scores.

```
--arch transformer
--share-all-embeddings
--encoder-layers 5
--decoder-layers 5
--encoder-embed-dim 512
--decoder-embed-dim 512
--encoder-ffn-embed-dim 2048
--decoder-ffn-embed-dim 2048
--encoder-attention-heads 2
--decoder-attention-heads 2
--encoder-normalize-before
--decoder-normalize-before
--dropout 0.4
--attention-dropout 0.2
--relu-dropout 0.2
--weight-decay 0.0001
--label-smoothing 0.2
--criterion label_smoothed_cross_entropy
--optimizer adam
--adam-betas '(0.9, 0.98)'
--clip-norm 0
--lr-scheduler inverse_sqrt
--warmup-update 4000
--warmup-init-lr 1e-7
--lr 1e-3 --min-lr 1e-9
--max-tokens 4000
--update-freq 4
--max-epoch 100
--save-interval 10
```

Figure 1: The baseline `flores` model settings[9] for the NMT training from scratch with `fairseq`

MBART For mBART evaluation, we initialize the weights of transformer with the mBART bilingual pre-training. We used monolingual text from CommonCrawl with denoising objective to pre-train the transformer. We trained 2 bilingual mBART models, one with English and Pashto text and another with English and Khmer text. Both these models were pre-trained with batch size of 256 for 500,000 updates, which took about 57 hours on 16 V100 GPUs.

Continued training on the filtered subsets uses some different parameter settings, as listed in Figure 2. This continued training is faster; it takes about half as much time.

6 Results

In this section we present the results of the shared task evaluation. We added additional unofficial condition at 2, 3, and 7 million English words, to better observe tendencies.

6.1 Core Results

The results are reported in Table 9 (Pashto) and Table 10 (Khmer). The tables contains the BLEU

[9] https://github.com/facebookresearch/flores#train-a-baseline-transformer-model

```
--dropout 0.1
--attention-dropout 0.1
--relu-dropout 0.0
--weight-decay 0.0
--label-smoothing 0.1
--adam-eps 1e-06
--lr 0.0001
--max-update 100000
--patience 10
```

Figure 2: Different model settings for continued training of the provided mBART model. The other settings are the same.

scores for

- development test set and final test set
- neural machine translation from scratch and mBART pre-training
- 2, 3, 5 and 7 million word subsets.

The official scoring is for the 5 million word data settings on the final test set. In the table, we highlight cells for the best scores for each of these settings, as well as scores that are close to it. Results for the unofficial 2, 3 and 7 million word baseline are shown without highlighting.

For almost all submission the highest BLEU scores is reached with subsets of 5 million words. There is also fairly high consistency between relative performance under training from scratch and mBART training. The best showings are by Alibaba and Huawei, followed by NRC and UA-Prompsit, with Microsoft still competitive. Other submissions score at least 1 BLEU points behind these.

Participants that also worked on sentence alignment of the provided document pairs were able to outperform the provided sentence pairs. The peak for these submissions shifts in most cases to the 7 million word subset. So, they were able to extract more useful sentence pairs. The best submissions for this setup comes from Bytedance. They outperform the provided sentence pairs and LASER scores by +3.8 BLEU (from 7.7 to 11.5) for Pashto from-scratch, +2.6 BLEU (from 10.3 to 12.9) for Pashto mBART, +4.3 BLEU (from 8.4 to 12.7) for Khmer from-scratch, +2.6 BLEU (from 12.9 to 15.5) for Khmer mBART.

6.2 Variance in the Evaluation

During the exploration of the evaluation protocol, we had some concerns about the stability of the BLEU scores obtained from training runs on a data set. This concern was reinforced by feedback from participants who did not match the baseline scores that we reported on the shared task web page.

To assess this, we executed three training runs for each subset of 5 million words selected from participant submissions. The resulting scores vary at most by 0.3 BLEU points for an identical training corpus, and differ most frequently just 0.1 BLEU point difference or are identical across all runs. The official reported results in Tables 9 and 10 are the average score across these three runs.

There may be higher differences for training on different hardware. We used a single NVidia GeForce GTX 1080ti GPU.

6.3 Average Sentence Length

Given the quality scores, subsets are selected by including the highest ranked sentence pairs until the total number of English words in these sentences reaches the specified size. So, if a quality scores prefers shorter sentences, more sentences are selected. It is not clear in general, all things being otherwise equal, if shorter or longer sentences are better for training machine translation systems.

What choices did the participants make in their quality scores? Table 11 and Table 12 show the number of sentences and the corresponding average number of words per sentence for the official subsets for all submissions. The average sentence length differs quite significantly, ranging from 12.3 to 29.0 words per sentence for Pashto, and 17.0 to 27.3 words per sentence for Khmer. Cross-referencing this against the effectiveness of the scores, methods that selected shorter sentences on average performed better.

In contrast to this, the average sentence length of submissions that also tackled sentence alignment is longer when compared to each participant's filtering-only submission.

6.4 Diversity of Submissions

The different submissions subselect different sentences, but how different are they?

Tables 13 and 14 give detailed statistics about how many sentence pairs the subsets of any two submissions for the two languages and two data conditions have in common.

The tables show for the 5 million word subset selected for each submission how many sentence pairs it contains (e.g., AFRL: 172,145), how many

Table 12: Number of sentences and the corresponding average sentence length (counting English words) for Khmer.

sentence pairs are unique to this submission's subset (e.g., AFRL: 7.6% of the 172,145 sentence pairs) and how many are in common with other submission (e.g,, 59.2% of AFRL's subset are also in Alibaba's subset).

The leading submissions show mostly about 60% overlap, although there are also more similar submissons (Alibaba's and Huawai's share around 80% of sentence pairs). The alignment submissions tend to be quite different, not surprisingly.

7 Conclusion

We report on the findings of the WMT 2020 Shared Task on Parallel Corpus Filtering and Alignment. Ten participants used a variety of methods that gave quite different results, as measured by translation quality, optimal subset sizes, sentence length, etc. We hope that this task provides a benchmark for future research and improvements on this task.

Abstract

We report the results of the WMT20 shared task on Quality Estimation, where the challenge is to predict the quality of the output of neural machine translation systems at the word, sentence and document levels. This edition included new data with open domain texts, direct assessment annotations, and multiple language pairs: English–German, English–Chinese, Russian–English, Romanian–English, Estonian–English, Sinhala–English and Nepali–English data for the sentence-level subtasks, English–German and English–Chinese for the word-level subtask, and English–French data for the document-level subtask. In addition, we made neural machine translation models available to participants. 19 participating teams from 27 institutions submitted altogether 1374 systems to different task variants and language pairs.

1 Introduction

This shared task builds on its previous eight editions to further examine automatic methods for estimating the quality of neural machine translation (MT) output at run-time, without the use of reference translations. As in previous editions, it includes the (sub)tasks of word-level, sentence-level and document-level estimation. Important elements introduced this year are: a variant of the sentence-level task where sentences are annotated with *direct assessment* (DA)[1] scores instead of labels based on post-editing; a new multilingual sentence-level dataset mainly from Wikipedia articles, where the source articles can be retrieved for document-wide context; the availability of NMT models to explore system-internal information for the task.

In addition to advancing the state of the art at all prediction levels, our main goals are:

- To create a new set of public benchmarks for tasks in quality estimation.
- To investigate models for predicting DA scores and their relationship with models trained for predicting post-editing effort,
- To study the feasibility of multilingual (or even language independent) approaches to QE.
- To study the influence of source-language document-level context for the task of QE.
- To analyse the applicability of NMT model information for QE.

We have three subtasks: Task 1 aims at predicting DA scores at sentence level (Section 2.1); Task 2 aims at predicting post-editing effort scores at both sentence and word levels, i.e. words that need editing, as well as missing words and incorrect source words (Section 2.2); Task 3 aims at predicting a score for an entire document as a function of the proportion of incorrect words in such a document, weighted by the severity of the different errors (Section 2.3).

Tasks make use of large datasets produced from either post-editions or DA annotations, or error annotation, all done by professional translators. The text domains vary for each subtask. Neural MT systems were built on freely available data using an open-source toolkit to produce translations, and these models were made available to participants. We provide new training and test datasets for Tasks 1 and 2, and a new test set for Task 3. The datasets

[1]We note that the procedure followed for our data diverges from that proposed by Graham et al. (2016) in three ways: (a) we employ fewer but professional translators to score each sentence, (b) scoring is done against the source segment (bilingual annotation) and not the reference, and (c) we provide translators with guidelines on the meaning of ranges of scores.

Proceedings of the 5th Conference on Machine Translation (WMT), pages 743–764

and models released are publicly available. Participants are also allowed to explore any additional data and resources deemed relevant.

Baseline systems were entered in the platform by the task organisers (Section 3). The shared task uses CodaLab as submission platform, where participants (Section 4) could submit up to 30 systems for each task and language pair. Results for all tasks evaluated according to standard metrics are given in Section 5, while a discussion on the main goals and findings from this year's task is presented in Section 6.

2 Subtasks

In what follows we give a brief description for each subtask, including the datasets provided for them.

2.1 Task 1: Predicting sentence-level DA

This task consists in scoring translation sentences according to their perceived quality score – which we refer to as direct assessment (DA). For that, a **new dataset**, was created containing seven languages pairs using sentences mostly from Wikipedia[2]. These language pairs are divided into 3 categories: the high-resource English→German (En-De), English→Chinese (En-Zh) and Russian→English (Ru-En) pairs; the medium-resource Romanian→English (Ro-En) and Estonian→English (Et-En) pairs; and the low-resource Sinhala→English (Si-En) and Nepali→English (Ne-En) pairs.

Translations were produced with state-of-the-art transformer-based NMT models trained using publicly available data and the fairseq toolkit (Ott et al., 2019); and were manually annotated for perceived quality. The quality label for this task ranges from 0 to 100, following the FLORES guidelines (Guzmán et al., 2019). According to the guidelines given to annotators, the 0-10 range represents an incorrect translation; 11-29, a translation with few correct keywords, but the overall meaning is different from the source; 30-50, a translation with major mistakes; 51-69, a translation which is understandable and conveys the overall meaning of the source but contains typos or grammatical errors; 70-90, a translation that closely preserves the semantics of the source sentence; and 91-100, a perfect translation.

[2]This dataset is a superset of MLQE (Fomicheva et al., 2020c) which included 6 language pairs and is sourced entirely from Wikipedia. The newly-added English-Russian DAs follow the same guidelines, but come from diverse sources.

Statistics on the dataset are shown in Table 1. More details are given in Fomicheva et al. (2020a). The complete data can be downloaded from the public repository[3].

Participation was encouraged for each language pair and also for the **multilingual variant** of the task, where submissions had to include predictions for all six Wikipedia-based language pairs (all except Ru-En). The latter aimed at fostering work on language-independent models, as well as models that can leverage data from multiple languages.

2.2 Task 2: Predicting post-editing effort

This task follows from previous editions of the WMT shared task and consists in scoring translations according to the proportion of their words that need to be fixed using HTER as label, i.e. the minimum edit distance between the machine translation and its manually post-edited version, as well as detecting where errors are in the translation of source sentences. It uses a subset of the languages from Task 1, namely the two high-resource language pairs (En-De and En-Zh, Table 1).

Sentence-level post-editing effort The label for this task is the percentage of edits that need to be fixed (HTER). Starting with the En-De and En-Zh source-machine translation segment pairs, the machine translation sentences were post-edited by two human translators, one per language, who are paid editors from the Unbabel community. The two translators had no access to the direct assessments above. In other words, the DA and HTER annotations were collected independently.

The average human translation error rate between the machine translated text and the post-edited text was 0.32 for En-De, and 0.62 for En-Zh. HTER labels were computed using TERCOM [4] with default settings (tokenised, case insensitive, exact matching only), with scores capped to 1.

Word-level errors This variant evaluates the extent to which we can detect word-level errors in MT output. Based on the post-edited translations, as described above, we annotate each token of the target and the source sentence, as well as word omission errors. The code to produce this set of tags from any prior WMT corpora is available for

[3]https://github.com/sheffieldnlp/mlqe-pe

[4]https://github.com/jhclark/tercom

	Sentences			Tokens				
Languages	Train	Dev	Test	Train	Dev	Test	DA	PE
En-De	7,000	1,000	1,000	114,980	16,519	16,371	✓	✓
En-Zh	7,000	1,000	1,000	115,585	16,307	16,765	✓	✓
Ru-En	7,000	1,000	1,000	82,229	11,992	11,760	✓	
Ro-En	7,000	1,000	1,000	120,198	17,268	17,001	✓	
Et-En	7,000	1,000	1,000	98,080	14,423	14,358	✓	
Ne-En	7,000	1,000	1,000	104,934	15,144	14,770	✓	
Si-En	7,000	1,000	1,000	109,515	15,708	15,821	✓	

Table 1: Statistics of the data used for Task 1 (DA) and Task 2 (PE). The number of tokens is computed based on the source sentences.

download.[5] More specifically, the following types of labels were produced:

- **Source side:** Each word in the source side is labelled as OK (correctly translated) or BAD (caused a translation error).
- **Target side:** Each word in the target side is labelled as OK (a correct translation) or BAD (should be replaced or deleted). Additionally, we consider gap 'tokens' at the beginning of the sentence, at the end and between each two words. They are labelled OK if no word should be inserted in that position (according to the post-edited version), and BAD otherwise.

In order to obtain the labels, we first align source and MT using the IBM Model 2 alignments from FastAlign (Dyer et al., 2013), and compute edit distances between the generated and post-edited translations with TERCOM, using default settings and disabled shifts.

2.3 Task 3: Predicting document-level MQM

This task consists in finding document-level translation errors and estimating a quality score according to the amount of minor, major, and critical errors present in the translation. The predictions are compared to a ground-truth obtained from annotations produced by crowd-sourced human translators from Unbabel community.

Each document contains zero or more errors, annotated according to the MQM taxonomy[6], and may span one or more tokens, not necessarily contiguous. Errors have a label specifying their type, such as wrong word order, missing words, agreement, etc. They provide additional information, but do not need to be predicted by the systems. Additionally, there are three severity levels for errors: *minor* (if it is not misleading nor changes meaning), *major* (if it changes meaning), and *critical* (if it changes meaning and carries any kind of implication, possibly offensive).

Figure 1: Example of fine-grained document annotation. Spans in the same color belong to the same annotation. Error severity and type are not shown for brevity.

Figure 1 shows an example of fine-grained error annotations for a sentence. Note that there is an annotation composed by two discontinuous spans: a whitespace and the token *Grip* — in this case, the annotation indicates wrong word order, and *Grip* should have been at the whitespace position.

Document-level scores were then generated from the word-level errors and their severity using the method described in Sanchez-Torron and Koehn (2016, footnote 6). Namely, denoting by n the number of words in the document, and by n_{min}, n_{maj}, and n_{cri} the number of annotated minor, major, and critical errors, the final quality scores were computed as:

$$\text{MQM} = 1 - \frac{n_{minor} + 5n_{major} + 10n_{crit}}{n} \quad (1)$$

[5] https://github.com/deep-spin/qe-corpus-builder

[6] Multidimensional Quality Metrics; see http://www.qt21.eu/mqm-definition/definition-2015-12-30.html for details.

Note that MQM values can be negative if the total severity exceeds the number of words.

As this year's dataset, we reused the training data from previous years, adding the test sets from 2018 and 2019 to the training set, keeping the same development set from 2019, and released a new test set. The documents are short product title and descriptions in English, extracted from the Amazon Product Reviews dataset (McAuley et al., 2015; He and McAuley, 2016) (Sports and Outdoors category). The documents were machine translated into French using a state of the art online neural MT system. The dataset statistics are presented in Table 2.

3 Baseline systems

Sentence-level baseline systems: For Tasks 1 and 2, both word and sentence-level, we used the LSTM-based Predictor-Estimator approach (Kim et al., 2017), implemented in OpenKiwi (Kepler et al., 2019b). The Predictor model was trained on the same parallel data as the NMT systems for each language pair (made available at the task website),[7] while the the Estimator was trained on the $7,000$ QE labelled data for each task.

Word-level baseline systems: For Task 2, we also used the Predictor-Estimator as above, but it was trained to predict jointly word-level tags and sentence-level scores.

Document-level baseline system: For Task 3, similarly as last year, we used a baseline which treats sentences independently and casts the problem as word-level QE, such that all words and gaps within an error span are given the tag BAD. We then trained a Predictor-Estimator model, regrouping any contiguous sequence of tokens tagged as BAD in a single error annotation. In order to get MQM scores, instead of computing the value according to its definition, we compute it simply as 1 minus the the ratio of BAD tags.

4 Participants

Table 3 lists all participating teams submitting systems to any of the tasks, and Table 4 report the number of successful submissions to each of the sub-tasks and language pairs. Each team was allowed up to two submissions for each task variant and language pair. In the descriptions below, participation in specific tasks is denoted by a task identifier (T1 = Task 1, T2 = Task 2, T3 = Task 3).

Bergamot-LATTE (T1): Bergamot-LATTE submitted two systems to the two variants of sentence-level predictions: (i) a black-box approach based on pre-trained representations; (ii) an unsupervised glass-box approach that leverages information extracted from the neural MT system. The black-box model consists of stacking a 2-layer multilayer perceptron on the vector representation of the CLS token from the contextualised representation from XLM-R(Conneau et al., 2020), using both the source and the target sentences as input. The glass-box approach explores the best-performing unsupervised quality indicators presented in Fomicheva et al. (2020c) that rely on uncertainty quantification based on the Monte Carlo dropout method: D-TP and D-Lex-Sim.

Bergamot (T1, T2): Bergamot explores recent work on glass-box QE that exploits NMT output distribution and attention to capture uncertainty as a proxy to MT quality. Specifically, they use three groups of unsupervised quality indicators described in Fomicheva et al. (2020c) as features for a regression model.

Bering Lab (T2): Bering Lab proposes a fine-tuned version of a pre-trained XLM-R model. The model is first trained on a huge artificial QE data that is created by (i) translating a parallel corpus with an OpenNMT system; and (ii) using the TER tool to produce artificial labels for both word- and sentence-levels. The model is then fine-tuned using the shared task's data. For predictions at word-level, the final hidden vector of each token, including the <S>, is fed into a linear layer with sigmoid activation in order to predict the probability of each of these token to be BAD. Quality labels for tokens and gaps are predicted separately with two distinct binary classification layers. For predictions at sentence-level, the final hidden vector of the first <S> token, considered as a pooled representation, is fed into two linear layers with $tanh$ activation. Submitted predictions are results of an ensemble of 5 models trained with different seeds: averaged predictions for sentence-level, and majority voting for word-level.

Table 4: Number of submissions to each sub-task and language-pair at the WMT20 Quality Estimation shared task. In the results (Section 5) we only report the top two submissions per team for each task and language pair.

Elturco.AI (T2): Elturco.AI uses a generative model and a discriminative model, inspired by Electra (Clark et al., 2020). The two models are jointly trained on a parallel corpus, in order to create increasingly difficult artificial samples for quality estimation. The generative model consists of a transformer encoder and two transformer decoders, for forward and backward direction. In addition to predicting tokens, it is also trained to predict gap locations on the target side given the source sentence and left and right contexts on the target side. Distorted translations are generated by sampling on generator outputs on token and gap locations, which can be shorter or longer than the original translation. The distorted translations are compared to original translations for generating token and gap tags. The discriminator, a transformer encoder-decoder with full attention mask on the decoder side, is trained to predict the generated tags given the source and distorted translation. Once trained, the discriminator is fine-tuned on the actual quality estimation dataset.

FVCRC (T1): FVCRC's system builds on BERTScore, a text generation evaluation system based on pretrained BERT contextual embeddings, originally for Metrics tasks. By

using pre-trained multilingual BERT-based model, they experiment with BERTScore on QE tasks. Without reference translations, it makes more errors in terms of word (or sub-word) alignments when perform greedy matching on pairwise cosine similarity, which is believed to be main cause of its drop of performance in QE tasks. They introduce GIZA++ word (subword) alignments and n-grams similarity matching to tackle misalignments and sentence perplexity of candidate translation as additional information to the evaluation score. Otherwise, the default setting of BERTScore (Zhang* et al., 2020) is used: pre-trained bert-base-multilingual-cased and xlm-mlm-100-1280 for embedding extraction, with a single model. This system is not trained on human labels (DA) and is not optimised on additional data.

HW-TSC (T2): HW-TSC submissions follows the Predictor-Estimator architecture (Kim et al., 2017), with a pre-trained Transformer as Predictor, and task-specific classifiers and regressors as Estimators. HW-TSC uses a unified model to solve both word- and sentence-level tasks, trained under multi-task learning. To improve the transfer-learning efficiency across tasks while preventing over-fitting, a Bottleneck Adapter Layer (Houlsby et al., 2019) is added to the Transformer after the self-attention and the feedfoward layers, while keeping the original parameters of the Transformer model fixed.

IST & Unbabel (T1, T2, T3): IST & Unbabel submitted two systems per task variant: OPENKIWI-BASE and KIWI-GLASS-BOX-ENSEMBLE for predicitons at both word- and sentence-levels; KIWI-DOC and KIWI-DOC-IOB for document-level predictions. OPENKIWI-BASE is based on the re-implementation of the Predictor-Estimator architecture (Kim et al., 2017) available in OpenKiwi (Kepler et al., 2019b): the Predictor model is replaced with pre-trained contextualised representations (such as BERT or XLM-R) and the bi-LSTM Estimator is replaced by linear layers. KIWI-GLASS-BOX-ENSEMBLE is similar to OPENKIWI-BASE with a bottleneck layer introduced in the Estimator in order to concatenate the features extracted from the Predictor, with sentence-level uncertainty features extracted from the NMT system provided by the shared task. Those glass-box features are based on work by Fomicheva et al. (2020c) and exploit entropy measures at prediction time. Unlike OPENKIWI-BASE, the KIWI-GLASS-BOX-ENSEMBLE model is trained for source, target and sentence level predictions simultaneously, using a multi-task learning approach. KIWI-DOC is the same as in Kepler et al. (2019a) while KIWI-DOC-IOB frames the task of annotating as Name Entity Recognition task: the severity annotations are projected to tags in IOB format (‘O‘, ‘B-major‘, ‘I-major‘, ‘B-critical‘, etc.) and the model is trained with a CRF output layer to enforce correctness of the tag-sequence at prediction time. The predicted tags are converted into annotations without the resort to a grouping and labelling heuristic.

JXNU-CCLQ (T1): JXNU-CCLQ proposes a model composed of a Transformer bottleneck layer and a bidirectional LSTM. The parameters of the Transformer bottleneck layer are first optimised with a bilingual parallel corpus, and the entire model is then fine-tuned on the training quality labelled dataset of the shared task. At test time, the translation outputs, which are estimated with teacher forcing and special masking, are put together with the source sentences and put through a unified neural network model to predict the quality of the translations.

Mak (T1): Mak represents the source and its translation sentence pairs as a set of 70 black-box sentence-level features extracted with Quest++(Specia et al., 2015), using the resources used to train the English-Russian NMT system (Ng et al., 2019). Those features are then fitted into a support vector regressor with default settings.

NICT Kyoto (T2): The English–German and English-Chinese sentence-level QE systems for Task 2 are ensembles of pre-trained cross-lingual language models (XLM) (Conneau and Lample, 2019), fine-tuned in a multi-task fashion with two linear output layers for sentence and word-level quality estimation. A total of 8 XLM models with various masking hyper-parameters were domain-adapted

using a subset of the additional resources provided by the QE shared task organisers, as well as a subset of the WikiMatrix corpus [2]. The translation language model training approach (TLM) was used before fine-tuning the XLM models for the QE task, complemented with a novel self-supervised learning task which aims to model errors inherent to machine translation outputs.

NiuTrans (T1, T2, T3): For Task 1, NiuTrans explored the combination of pre-trained models and multi-task learning. They used three different model settings, including multilingual-bert (∼200M parameters), xlm-roberta-base (∼300M parameters) and xlm-roberta-large (∼600M parameters). They continued pre-training all models on the WMT dataset and utilised task adaptive pre-training to further boost the models' performance. The output of different models was combined using a weighting scheme to get final predictions. For Task 2, an ensemble of 10 transformer-based predictor-estimator models was used, with multi-task training for the word-level tasks. Each single model contains 10M parameters. They also submitted an ensemble result of multilingual-bert and xlm-roberta-base for sentence-level scoring tasks. For Task 3, they used an ensemble of 8 predictor-estimator models and multi-task training for the word-level subtask. The single model contains 150M parameters. For the scoring subtask, they explored an ensemble of linear regression models and pre-trained models. They also used WMT 2014 English-French dataset for fine-tuning.

NJUNLP (T2): This system is an ensemble using NuQE and QUETCH models (Kepler et al., 2019b), as well as the QE Brain model (Fan et al., 2019). In addition to these pre-existing models, the ensemble also uses a masked version of the QE Brain, where some tokens in the translation are masked during training, and a masked language model (Devlin et al., 2018). For sentence-level, the different models are used as feature extractors, which are used as inputs of a dense layer to produce the predictions. For word-level, they use majority voting to ensemble the different models.

Papago (T1, T3): Papago's submission for Task 1 En-De is an ensemble of three models based on pre-trained contextualised representations: multilingual BERT (mBERT), XLM-Masked-Language-Modelling (XLM-MLM), and XLM-Causal-Language-Modelling (XLM-CLM). Three scores were produced from these models: an extension of BERTScore using the multilingual BERT model, SentenceBERT score (Reimers and Gurevych, 2019), and target (German) language model score using a pre-trained GPT-2 model. Additionally, the scores were computed for synthetic data created using WMT News translation data by randomly performing different methods, including swapping word order, omiting words or repeating phrases. The three models are pre-trained from these data in a multi-task regression setting. Lastly, these pre-trained models are fine-tuned using the QE corpus. For Task 3, the submitted system uses an ensemble of four models leveraging either multilingual BERT or XLM. The training scheme is very task-oriented: erroneous sentence pairs and their pseudo-MQM scores are generated from Europarl and this QE task's training corpus.

RTM (T1, T2): For Task 1 and Task 2's sentence-level prediction, the RTM model treats QE as a parallel semantic similarity prediction task within machine translation performance prediction (MTPP) or a monolingual semantic similarity when the source or the target language are unknown or have scarce resources. En-De and Ru-En were modelled as parallel MTPP and the rest as monolingual MTPP using only the English side of the training and development datasets. Machine learning algorithms including ridge regression, SVR, and regression trees were used and the submissions were constrained to the resources provided. RTM selects a subset of parallel and monolingual text for each translation direction.

TMUOU (T1): TMUOU proposes an ensemble of four regression models based on XLM-R large: model 1 uses the final hidden vector of the CLS token; model 2 concatenates the feature of model 1 with the mean of the final hidden vector of each token; models 3 and 4 are based on models 1 and 2, respectively, but

adds a special token for language identification at the beginning of each sentence. The ensemble model is a gradient boosting regressor that features the predictions of these four models, the sentence probability of the target translation system, and one-hot vectors that indicate both the source and target languages.

Tencent (T2): Tencent-TTL's submission for the sentence-level Task 2 use a predictor-estimator model. They use two predictors as feature extractors: a transformer trained with WMT provided parallel corpus and a fine-tuned cross-lingual language model (XLM). For the XLM-based predictor, it produces two kinds of contextual token representations, i.e., masked representations and non-masked representations. For transformer-based predictor, only the non-masked representation is produced. The estimator was trained with LSTM or Transformer. Finally, they ensembled the systems with different models and the same model with different parameters using logistic regression to produce a single sentence-level prediction.

TransQuest (T1, T2): TransQuest proposes two architectures: MONOTRANSQUEST and SIAMESETRANSQUEST, both using pre-trained XLM-R large transformer model. The MONOTRANSQUEST architecture uses the computed CLS token pooled representation from a single transformer model and uses it as input of a softmax layer that predicts the quality score of the translation. The SIAMESETRANSQUEST architecture encodes both the source sentence and its translation with two separate XLM-R transformer models. For each transformer model, the it computes the mean of all output vectors of the input words, and applies the cosine similarity measure between the two outputs. The final submission is an ensemble of the two architectures.

WL Research (T1): WL's NUBIA method has three modules: a neural feature extractor, an aggregator and a calibrator. The feature extractor consists of different transformer-based architectures fine-tuned on relevant tasks of language evaluation such as semantic similarity (RoBERTa model fine-tuned on STS-B), logical inference (RoBERTa fine-tuned on MNLI) and sentence likelihood (GPT2 perplexity score). The aggregator uses the features extracted by the transformers as well as non-neural features such as hypothesis sentence length and is trained to predict the quality of the hypothesis sentence. These features are then used to train a 10 hidden layer neural network. Given that NUBIA takes as input sentences in English, as pre-processing step, Google Translate was used to translate either the non-English candidate or source to have both in English.

XC (T1): This was a multilingual system trained using TransQuest (with BERT embeddings bert-base-multilingual-cased) and data for all language pairs concatenated. An attempt was also made to use project the BERT source and target sentence embeddings into a space where they are highly correlated using CCA (Canonical Correlation Analysis) followed by an MLP regressor trained to predict the quality score, but this did not perform as well as a vanilla TransQuest.

5 Results

5.1 Task 1

Submissions for Task 1 are **evaluated** against the true z-normalised direct assessment label using Pearson's r correlation score as primary metric. This is what was used for ranking system submissions. Mean Absolute Error (MAE), and Root Mean Squared Error (RMSE) were also computed as secondary metrics. Statistical significance on Pearson r was computed using William's test.[8]

Table 5 summarises the results for all language pairs, as well as the multilingual variant, in terms of Pearson's r correlation with direct assessments, ranking systems by their average performance for all language pairs (using 0 as Pearson score for other languages). In the Appendix, Tables 11, 12, 13, 14, 15, 16, 17 and 18 provide the detailed results for all language pairs and the multilingual variant, ranking participants by their performance for each of these cases. The detailed tables show a striking difference in performance by Pearson scores versus MAE/RMSE, especially for the top systems. This requires further investigation.

Best performers The two top performing systems, TransQuest and Bergamot-LATTE (black-

Table 5: Pearson correlation with direct assessments for the submissions to WMT20 Quality Estimation Task 1. For each language pair, results marked in bold correspond to the winning submissions, as they are not significantly outperformed by any other system according to the Williams Significance Test (Williams, 1959). Baseline systems are highlighted in grey; † indicates teams that have been identified as having submitted more systems than the allowed limit to the leaderboard; ‡ indicates Codalab username of participants from whom we have not received further information.

box) perform the same or very closely for all language pairs. Both make use of the XML-R large pre-trained representations, and ensembles. This is clearly a booster, as these systems achieve almost double the correlation of the baseline. Note that the baseline also uses pre-trained word embeddings, but these are obtained using much smaller datasets: those used to train the NMT models for each respective language pair.

Except for a few systems for some language pairs, the vast majority of submissions outperform the baseline system, often by a large margin, except for Russian-English which had fewer submissions and where 1/3 of the systems are below the baseline. It is hard to make any conclusions about this difference across languages as Russian-English systems that are below the baseline did not submit systems for other languages. In relative terms, the improvement over the baseline for top systems in this language is similar to the other language pairs. The range of performances is remarkably wide, with the winning systems often doubling the Pearson correlation of the bottom pack, notably for English-Chinese and English-German.

To gain a better understanding in the performance of different QE approaches for different language pairs, Figure 2 shows the scatter plots for the baseline and the best performing system for each language pair. Note the remarkable difference in correlation between the baseline and the top performers across languages. In the figures, we can visualise the substantial gains are achieved, largely due to the use of strong pre-trained representations.

High-resource performance MT quality for the high-resource language pairs, in particular English–German, was the most challenging to predict. As discussed in Fomicheva et al. (2020a), the MT outputs for this language pair have little variability in terms of perceived MT quality. The vast majority of translations were assigned high scores during DA evaluation, which makes it difficult to capture any meaningful variation between the DA scores. We observe that the results for HTER prediction for this language pair are more positive, a difference which we discuss in Section 6.

Low-resource performance Interestingly, the results for the low-resource language pairs, Sinhala–English and Nepali–English, are comparable with the rest. The fact that the performance of the winning approaches based on multilingual pre-trained representations does not degrade for the low-resource language pairs is worth noticing. It could indicate that: (*i*) the source language does

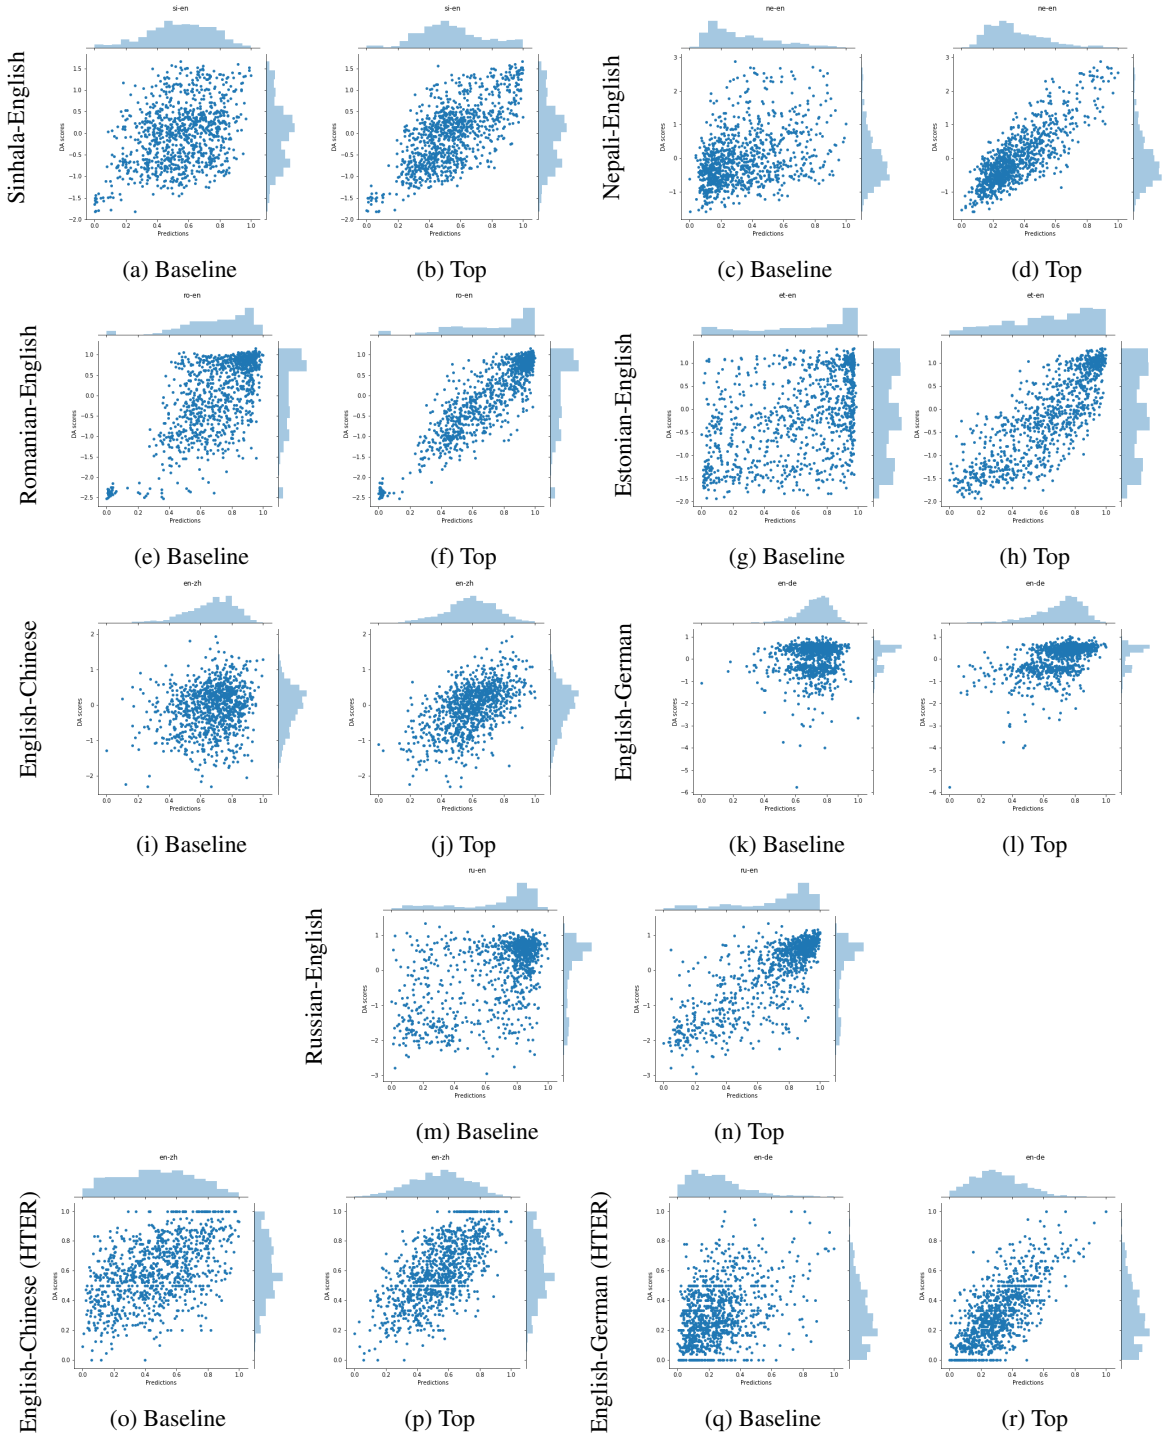

Figure 2: Scatter plots for the predictions against true scores for the baseline and top-performing systems. Sub-figures (a) through (n) show systems trained on direct assessment, while sub-figures (o) through (r) show systems trained on HTER. Predictions are scaled to $[0..1]$.

not have as high an impact on QE as the target language, which has been previously observed as a problem for QE with *partial-input* experiments (Sun et al., 2020); (*ii*) shared supervision on the target side is beneficial, and thus having more training data into English inherently benefits multiple languages; or (*iii*) the distribution of scores is more balanced for low- and medium-resource languages, which makes the task easier. To shed more light on this, for future shared tasks, we recommend having more low resource languages as the target language for QE, or more data with shared languages on the source.

High correlations Finally, for some language pairs the performance of the top system is very high, particularly for Romanian–English (Pearson $r = 0.91$). As shown in Figure 2f, there is a number of very low-quality sentences that the QE systems are able to successfully detect. By inspecting those cases, we find that they correspond to 'hallucinated' outputs from the Romanian–English MT system that do not have anything to do with the original sentences. Detecting such cases should be trivial for QE systems, which explains the particularly high correlation values for this language pair. This highlights a possible issue with using Pearson correlation to evaluate the performance of QE systems: strong correlations can be achieved by having an over-representation extreme values (i.e. really bad or really good translations), and bad correlations can be an artefact of the lack of representation of extreme values (as in the case of English-German).

5.2 Task 2

Sentence-level post-editing effort: For this task variant, **evaluation** was performed against the true HTER label using the same metrics as in Task 1, with Pearson's r correlation score as the primary metric. Statistical significance on Pearson r was computed using the William's test.

Table 6 summarises the results for English–German and English–Chinese tracks, ranking systems by their average performance for the two language pairs (with 0 as Pearson score for languages without systems). In the Appendix, Tables 19 and 20 show the detailed evaluation results for the two language pairs, ranking participating systems best to worst using Pearson's r correlation as primary key.

For English–German, the two top performing systems, HW-TSC and Bering Lab, are substantially ahead of the other participants' systems, with a considerable advantage for HW-TSC, which is the top system with statistical significance. For English–Chinese, Tencent and IST/Unbabel glass-box system were the top performing systems and neither outperforms the other; for this language pair, the range of Pearson scores achieved by participants' systems is much narrower than for English-German. Finally, for both language pairs, we see that all submissions outperform the baseline system by a large margin, most prominently for English–German.

Word-level errors For this task, the primary **evaluation** metric is Matthews correlation coefficient (MCC, Matthews, 1975). We also report the F_1-scores for the OK and BAD classes. Similarly to the 2019 edition, we evaluate separately the source and target side, with the latter including predictions on actual target words as well as gaps. The word-level results for Task 2 are summarised in Tables 7 and 8, ordered by the MCC metric on target errors.

The number of submissions per language pair was different, which limits any conclusions that can be made with respect to general rankings of systems. For English–German, the findings are similar to the sentence-level task: the Bering Lab and HW-TSC teams are the top performing systems by a great margin, with the former better at predicting source side errors and the latter slightly better at predicting target side errors. For English–Chinese, the range of scores is narrower, with HW-TSC, NICT Kyoto, and IST/Unbabel all performing very closely (with HW-TSC on top). For both language pairs, all systems performed above the baseline, and we also see that the scores for the source side are substantially lower than the target side.

5.3 Task 3

MQM score estimation For the document-level estimation task, submissions are evaluated in terms of Pearson's correlation r, as in Tasks 1 and 2, between the true and predicted document-level scores. Participants results are shown in Table 9. This task attracted fewer participants than the other two, probably because it is more complex. Papago has the best results, with a considerable gap to the IST/Unbabel, which in turn also were well ahead of the baseline.

Fine-grained annotations Fine-grained annotations are evaluated as follows. For each error anno-

tation a_i^s in the system output, we look for the gold annotation a_j^g with the highest overlap in number of characters. The precision of a_i^s is defined by the ratio of the overlap size to the annotation length; or 0 if there was no overlapping gold annotation. Conversely, we compute the recall of each gold annotation a_j^g considering the best matching annotation a_k^s in the system output,[9] or 0 if there was no overlapping annotation. The document precision and recall are computed as the average of all annotation precision in the corresponding system output and recalls in the gold output; and therewith we compute the document F_1. The final score is the unweighted average of the F_1 for all documents.

The annotation scores are shown in Table 10. Only one participant, IST/Unbabel submitted valid results, but still better than the baseline.

6 Discussion

In what follows, we discuss the main findings of this year's shared task based on the goals we had previously identified for it.

General progress. Overall, participating systems achieved very promising results, with the best performing submissions showing moderate to strong correlation for sentence-level DA and HTER prediction tasks. One reason for high correlation levels is likely to be that top performing systems are based on pre-trained representations. Like in other NLP tasks, for QE it had already been shown to substantially improve the results over models that do not use such representations, with heavier pre-trained embeddings contributing substantially more (Kepler et al., 2019a). Strong pre-trained embeddings such as XLM-R were used by most submissions this year.

When interpreting the results for all tasks, it should be noted that most of the participants use extremely resource-heavy systems, ensembles of multiple models with more than 500M parameters, which could make them difficult to use in practice. Reporting the number of parameters could be a good practice for the future.

Comparison to previous years submissions are not possible as they use very different datasets, except for Task 3, where a new test set was collected from the same initial larger dataset, but the training data is virtually the same. For the fine-grained version of the task, results are on par with last year (0.48 F1), while for the scoring variant the results this year are more encouraging: while the baseline remains similar (Pearson = 0.39 this year and 0.35 last year), the top system is significantly better this year: 0.57 Pearson instead of 0.37 last year.

Unfortunately, the document-level task still attracts very few participants, being naturally more difficult to model. However, document-level translation quality is a growing concern in the MT community, and we believe it is interesting that this task continues to exist, possibly with a different dataset and format, in the next editions.

Comparison between HTER and DA. Compared to the results from the previous editions of this shared task, participating systems show overall higher correlation with DA labels. Besides the QE systems getting much stronger, DA labels might be easier to predict, as HTER is a semi-automatic metric and may suffer from the same issues as TER, as it does not capture to what extent the overall quality of the sentence is affected by MT errors. We should note, however, that for the language pairs selected for post-editing this year (English–German and English–Chinese) the correlation is higher for HTER. A possible reason is a very skewed output distribution of the DA scores for these particular language pairs.

HTER and DA annotation capture different aspects of translation quality. In fact, as shown in Fomicheva et al. (2020a), the correlation between the two types of scores is fairly low. An interesting question is whether the approaches that perform best for predicting DA also achieve the best results for HTER. Figure 3 plots sentence-level Pearson correlation with HTER and direct assessments for the systems that participated in both tasks. While the systems with the highest and the lowest ranks are the same, results change considerably for the systems in the middle. Specifically, TransQuest is one of the winning submissions for the prediction of DA, but is outperformed by the submissions that use glass-box features, i.e. Bergamot and IST and Unbabel (Kiwi-glass-box) for the HTER task.

Multilingual approaches. Most of the participating approaches rely on pre-trained multilingual representations and use the provided data annotated with quality labels for fine-tuning. This shows the potential for multilingual prediction in these systems making them much more appealing in prac-

[9] Notice that if a gold annotation a_j^g has the highest overlap with a system annotation a_i^s, it does not necessarily mean that a_i^s has the highest overlap with a_j^g.

tice where having dedicated systems for each language pair may be infeasible. However, in the task most submissions built models specific to each language pair, and then submitted their predictions to the multilingual task. A notable exception is the Bergamot-LATTE team, where a single prediction model was trained for all languages.

Influence of source-language document-level context. To investigate the utility of document-level information, we offered to participants the title of the Wikipedia article where the sentences were extracted for Tasks 1 and 2. However, no participating system requested these additional labels, and therefore this remains an open question.

Applicability of NMT model information. Multiple submissions use glass-box features based on the information extracted from the NMT system in an unsupervised manner (Bergamot-LATTE), in a regression setting (Bergamot) or in combination with pre-trained representations (IST and Unbabel). Results show the potential of this approach. Although substantially outperformed by the top submissions that use pre-trained representations trained with very large amounts of data, glass-box approaches beat the baseline, which use the same amount of training data as the NMT system, by a large margin. These approaches might offer a better trade-off between accuracy and efficiency for cases where the NMT model is accessible.

New publicly available benchmarks. Creating the multi-language, multi-label dataset for this year's edition was a significant joint effort from various institutions, and we hope it will be useful for researchers in QE as well as in related areas. For example, Task 2 data was also used for the WMT20 Automatic Post-Editing task. We hope to continue adding data to this collection following the same principles, and that others will also contribute by adding other languages to it in the future. We made all submissions to the task available for

those interested in further analysing the results, investigating approaches for prediction ensembling, among others.

7 Conclusions

This year's edition of the QE Shared Task introduced a number of new elements: the largest number of languages ever, new types of annotation (direct assessment, in addition to labels derived from post-editing and manual error tagging), and number of samples annotated overall. It also attracted the largest number of teams and submissions. We believe the current set of tasks covers a broad enough range of challenges that are far from solved, such as improving performance for languages with skewed distributions, addressing low resource languages, predicting source words that lead to errors, multilingual or language-independent models, etc. In future editions, we hope to keep pushing for progress in these areas.

Acknowledgments

Marina Fomicheva, Frédéric Blain and Lucia Specia were supported by funding from the Bergamot project (EU H2020 Grant No. 825303). André Martins and Erick Fonseca were funded by the P2020 programs Unbabel4EU (contract 042671) and MAIA contract 045909), by the European Research Council (ERC StG DeepSPIN 758969), and by the Fundação para a Ciência e Tecnologia through contract UIDB/50008/2020. We would like to thank Camila Pohlmann and the Unbabel community team for monitoring the post-editing process. We thank IQT Labs for providing the Russian-English dataset for Task 1.

Findings of the WMT 2020 Shared Tasks in Unsupervised MT and Very Low Resource Supervised MT

Alexander Fraser

Center for Information and Language Processing, LMU Munich, Germany
fraser@cis.lmu.de

Abstract

We describe the WMT 2020 Shared Tasks in Unsupervised MT and Very Low Resource Supervised MT. In both tasks, the community studied German↔Upper Sorbian MT, which is a very realistic machine translation scenario (unlike the simulated scenarios used in particular in much of the unsupervised MT work in the past). We were able to obtain most of the digital data available for Upper Sorbian, a minority language of Germany, which was the original motivation for the Unsupervised MT shared task. As we were defining the task, we also obtained a small amount of parallel data (about 60000 parallel sentences), allowing us to offer a Very Low Supervised MT task as well. Six primary systems participated in the unsupervised shared task, two of these systems used additional data beyond the data released by the organizers. Ten primary systems participated in the very low resource supervised task. The paper discusses the background, presents the tasks and results, and discusses best practices for the future.

1 Introduction

There is no machine translation available for most of the approximately 7000 languages spoken on the planet Earth. This is because very limited or no parallel corpora are available. Research on unsupervised and very low resource machine translation is important for alleviating this problem. Unsupervised machine translation requires only monolingual data, while very low resource supervised machine translation uses very limited parallel data.

At WMT 2018 and WMT 2019, the first shared task (Bojar et al., 2018) and second shared task (Barrault et al., 2019) on Unsupervised Machine Translation (UMT), were held as part of the news translation track. In both 2018 and 2019 the scenarios simulated low resource setups using medium or high resource languages. In 2018, the language pairs were Turkish-English, Estonian-English and German-English. In 2019, we tested unsupervised systems for German to Czech unsupervised translation (where no German/Czech parallel data was allowed).

In the 2020 shared task we proposed a third edition on UMT, which aimed at a more realistic scenario, German to Upper Sorbian (and Upper Sorbian to German) translation. Upper Sorbian is a minority language of Germany that is in the Slavic language family (e.g., related to Lower Sorbian, Czech and Polish), and we provide here most of the digital data that is available for Upper Sorbian, as far as we know. The amount of monolingual data available for Upper Sorbian is quite small (see below), making unsupervised machine translation very challenging.

While working on the UMT task we were able to obtain a very small amount of parallel data (about 60000 parallel sentences) for this language pair, which allowed us to additionally offer the very low resource supervised translation task.

The exact tasks studied in the shared tasks were:

- Unsupervised Machine Translation: German to Upper Sorbian. Upper Sorbian to German.
- Very Low Resource Supervised Machine Translation: German to Upper Sorbian. Upper Sorbian to German.

The data used can be downloaded from the shared task webpage.[1]

This paper will give some background for the task, discuss the data made available (with a particular focus on considerations for benchmarks for future UMT and very low resource MT research), discuss how the tasks went with a presentation of the results, and then conclude.

Proceedings of the 5th Conference on Machine Translation (WMT), pages 765–771
Online, November 19–20, 2020.

2 Background

The 2020 shared tasks focused on the very low resource language Upper Sorbian (a Slavic minority language spoken in the Eastern part of Germany). The Sorbian language (referring to Upper Sorbian and Lower Sorbian) has a special protected status in the "Grundgesetz" of Germany (similar to a constitution).

Working with the Sorbian Institute[2] we initially prepared an unsupervised MT task. We expect this task to become a standard benchmark for unsupervised MT development. This task particularly relies on having high quality Upper Sorbian monolingual data, which we obtained from the Sorbian Institute and the Witaj Sprachzentrum. We also offered data which LMU Munich obtained through web crawling. Finally, the Sorbian Institute has also provided medium quality data which has not been quality checked.

The Witaj Sprachzentrum (Witaj Language Center[3]) then provided a small training corpus of German/Upper Sorbian parallel data, which was used in the Very Low Resource Supervised Machine Translation task. We expect this task to become a standard task for very low resource scenarios, and note that the results are important as they will directly inform efforts to create state-of-the-art machine translation systems for use by the Upper Sorbian community.

The Witaj Sprachzentrum provided development and "development test" (not blind test) sets for German to Upper Sorbian and Upper Sorbian to German translation. The development set is used to tune parameters, while the devtest set is used to measure progress using automatic metrics. The Witaj Sprachzentrum also provided the blind test sets, which were released just in time for the evaluation.

We note that CIS (LMU Munich), the Sorbian Institute and the Witaj Sprachzentrum hope to organize a task for Unsupervised Lower Sorbian translation in the near future.

LMU Munich would be interested in adding new typologically diverse languages as unsupervised and/or very low resource tasks in future WMT Shared Tasks.

3 Basic Tasks and Evaluation

We provide some basic details about the tasks and evaluation here.

Unsupervised MT: Unsupervised translation from German to Upper Sorbian, and unsupervised translation from Upper Sorbian to German. We allow the use of all German data released for WMT, except that the German side of the small parallel German/Upper Sorbian training corpus may not be used. All Upper Sorbian data we release may be used. No other language data may be used.

Very Low Resource Supervised MT: Supervised translation from German to Upper Sorbian, and supervised translation from Upper Sorbian to German. We allow the use of all German and Upper Sorbian data released for WMT, including the small parallel German/Upper Sorbian training corpus. Other WMT data for other languages may also be used. Upper Sorbian is a Slavic language which has strong similarities to Czech, so the German/Czech data we discuss below may be of particular interest for multilingual systems.

We used automatic metrics for the evaluation of this task. We believe that manual evaluation may not be so necessary for unsupervised MT and very low resource MT development, because automatic metrics worked well at relatively low translation quality levels in the past. Translation to Upper Sorbian would have been fairly difficult to evaluate in a human evaluation, as we do not have easy access to a large number of native speakers.

4 Data

We describe the data released for the two scenarios, Unsupervised and Very Low Resource Supervised.

The Unsupervised MT scenario allowed the use of all German data released for WMT, except that the German side of the small parallel German/Upper Sorbian training corpus could not be used. All Upper Sorbian data available on the web page was allowed. No other language data could be used (no parallel, no other monolingual data sets for any language except those explicitly listed as usable for Unsupervised).

The Very Low Resource Supervised MT scenario allowed the use of all German and Upper Sorbian data released for WMT, including the 60000 sentence parallel German/Upper Sorbian training corpus. Other WMT 2020 data for other languages were also allowed. Upper Sorbian is a Slavic language which is related to Czech, so the Ger-

man/Czech parallel data we briefly describe next were of particular interest for building multilingual systems. We would also like to express our thanks to the Opus project for the German/Czech parallel data.

In addition to training data, we also provided **development data**. Specifically, we provided development and test sets for German to Upper Sorbian and Upper Sorbian to German. These were usable for both Unsupervised and Very Low Resource. The dev set was intended for use for parameter tuning (and the participants were asked to not use it as a parallel training corpus). The test set was intended for system evaluation during development (likewise, the participants were asked to not use it as a parallel training corpus). We would like to thank Jindřich Libovický for creating the data splits and for work on the training data.

The specific data sets are presented in Table 1.

The translation output was submitted as real case, detokenized, and in SGML format. We used the Matrix for submission, thanks to Barry Haddow for assistance. The standard script wrap-xml.perl was used to create the sgm files for upload.

5 Results

In this section we discuss the results for the Unsupervised track, a non-constraint system that does not use parallel German/Sorbian data but does use German-English parallel data (which does not meet the constraints for the Unsupervised Task), and the Very Low Resource task.

We note that the absolute BLEU scores are surprisingly high, this may be due to unusually homogeneous train and test sets.

5.1 Unsupervised MT

There were four submissions to the Unsupervised MT which used only the allowed data for the track, see Table 2. The citations are listed in the table. Highlights of systems here included the use of transfer learning to obtain better initialization for the lower resource language and refinements of BPE, see the papers (and the analysis below) for further details.

5.2 Unsupervised MT with Multilingual Transfer Learning

Two primary submissions to Unsupervised MT were not restricted to the allowed data for the track, see Table 3. One system used data mined from German and Upper Sorbian Wikipedia, see (Dutta et al., 2020) for more details. The creators of the other system (Li et al., 2020) used parallel data for English to German to initialize an unsupervised system, which is a reasonable scenario to consider. This was highly effective. We suggest that this result be used as an initial benchmark for multilingual transfer-based unsupervised systems. We consider these results to be separate from the simpler unsupervised benchmark that was previously proposed. See the subsequent analysis and discussion for more details.

5.3 Very Low Resource MT

A Moses baseline from the Witaj Sprachzentrum using only the data from the shared task web page scored 46.36 for DE-HSB (BLEU-cased, 11b) and 47.70 for HSB-DE (BLEU-cased, 11b). The results for the shared task systems are presented in Table 4. Note that the last system did not submit a shared task paper.

6 Analysis

Overall we proposed two new benchmark tasks for low resource MT. The Unsupervised MT track can be used as a benchmark for testing new unsupervised MT approaches. The Very Low Resource track can be used as a benchmark for testing MT systems when one language has very little parallel data. Additionally, one system which was conceptually unsupervised (in that it used no parallel German-Upper Sorbian data), effectively defined a new benchmark, which we will call Unsupervised MT with Multilingual Transfer, by using additional English-German parallel data, see below.

6.1 Task Definitions

Unsupervised MT: The data released for the Unsupervised MT track should be considered to be a new realistic benchmark for testing unsupervised MT systems. Artetxe et al. (2020) (a best practices paper at ACL 2020) made a number of suggestions in terms of how to setup future Unsupervised MT research. The guidelines we set agree with their guidelines except with respect to one point. We disagree with Artetxe et al. in terms of whether development sets should be made available. The dev set is traditionally used for setting a small number of open parameters. Artetxe et al. argue that this data should not be made available, as it represent parallel data that is not really in spirit with

Monolingual Upper Sorbian Data	
sorbian_institute_monolingual.hsb.gz	Upper Sorbian monolingual data provided by the Sorbian Institute. This contains a high quality corpus and some medium quality data which were mixed together.
witaj_monolingual.hsb.gz	Upper Sorbian monolingual data provided by the Witaj Sprachzentrum (high quality).
web_monolingual.hsb.gz	Upper Sorbian monolingual data scraped from the web by CIS, LMU (thanks to Alina Fastowski). This should be used with caution, it is probably noisy, it might erroneously contain some data from related languages.
Monolingual German Data	
	See the news translation task web page for allowed monolingual German data. All monolingual German sets allowed in this years News task were allowed in both scenarios.
Upper Sorbian side of parallel training corpus	
train.hsb-de.hsb.gz	This file was usable for both the Unsupervised and Very Low Resource Supervised scenarios. In the Unsupervised scenario, it was used as a small high quality monolingual corpus.
German side of parallel training corpus	
train.hsb-de.de.gz	This file was not usable for Unsupervised.
Dev and Test Sets	
devtest.tar.gz	The participants were requested to please use dev to tune system parameters, and test to measure progress. These files were allowed in both tracks.
German/Czech Parallel Data	
	This data was not allowed for Unsupervised. For Very Low Resource MT we allowed all German/Czech parallel corpora obtainable from the Opus project. The de-cs corpora we particularly recommended using are: Europarl v8 and JW300 v1. These two corpora may be somewhat similar to the DE-HSB parallel training and test data, but this is far from certain.

Table 1: Data sets for both tasks.

Table 3: Two primary submissions to the Unsupervised MT Task using additional English-German parallel data (row 1) and German and Upper Sorbian monolingual data from Wikipedia (row 2).

the unsupervised MT paradigm. In practice one could create a "very very low resource" system by simply training a supervised system on this data. We however argue that system developers need to have access to standard dev and devtest sets in order to measure progress. Having access to a dev set simulates having access to, e.g., a native speaker of the low resource language, who is able to look at outputs during MT development and judge the changes in quality obtained through simple hyperparameter changes. In our view the use of a devtest set to measure BLEU (which is completely standard in all unsupervised MT research) is similar to this, and of course also represents a small amount of available parallel data. A further argument for our view is that having a designated dev set for parameter tuning strongly helps with replicability of results. However, it is important in our view that this data not be trained on (in terms of using it as a parallel corpus to training a supervised system). The restriction of the rest of the data to be monolingual and carefully controlled makes sense for the straightforward testing of bilingual unsupervised systems, but we describe an interesting different multilingual scenario next.

Unsupervised MT with Multilingual Transfer: SJTU-NICT submitted a system to Unsupervised MT which looked at the reasonable scenario of assuming that the high resource language (German for German-Upper Sorbian) has parallel corpora with another language. In their system they used an English-German parallel corpus to initialize their German-Upper Sorbian Unsupervised MT system. This makes their system conceptually a multilingual system. Another obvious choice would be to try German-Czech and/or German paired with another Slavic language (and in fact, in the Very Low Resource Track, this was a common strategy). There were no competing systems for this unplanned benchmark (which was essentially created by SJTU-NICT's submission), but we suggest that this result is also interesting for comparison in future research and intend to offer a new track for this scenario in the shared task next year.

Very Low Resource MT: Please see the shared task system descriptions to see the wide variation in the exact data used for the Very Low Resource task.

There was obviously a high level of interest overall in this task, and we already have plans to offer more tasks of this kind as well. This task is very interesting as even if an unsupervised MT system is actually deployed for a particular language pair, the users of the system can post-edit the output of that system and will soon therefore be interested in training higher quality supervised systems using the Very Low Resource scenario. The parallel data used in this track was in fact created manually by the Witaj Sprachzentrum in order to be used by the Upper Sorbian community in Germany (to train the baseline Moses system we mentioned in the results section, and for future neural machine translation work which will be informed by the results produced by the research community). As the result of the existence of this pipeline more data may become available in the future.

6.2 What Worked Well

We highlight four interesting trends in terms of the results. Two of the trends we observe here involve transfer learning (i.e., pretraining). For all three

System Name	DE-HSB	HSB-DE	citation
SJTU-NICT	60.7	58.5	(Li et al., 2020)
Helsinki-NLP	57.9	59.6	(Scherrer et al., 2020)
NRC-CNRC	57.3	58.9	(Knowles et al., 2020)
LMU-supervised-ensemble	56.5	57.6	(Libovický et al., 2020)
CUNI-Transfer	55.5	56.9	(Kvapilíková et al., 2020)
Brown-NLP-b	46.2	45.7	(Berckmann and Hiziroglu, 2020)
IITBHU-NLPRL-DE-HSB	45.9	47.9	(Baruah et al., 2020)

UdS-DFKI	40.9		(Dutta et al., 2020)
HierarchicalTransformer	38.2	40.1	

Table 4: Ten primary systems submitted to the Very Low Resource Task, sorted by DE-HSB BLEU score.

benchmarks (Unsupervised, Unsupervised with Multilingual Transfer, and Very Low Resource) transfer learning is a critical component of many or all systems. The trends we will discuss are transfer learning using monolingual corpora and transfer learning using bilingual corpora. For Unsupervised, transfer learning using monolingual corpora was an important aspect of successful systems. Please see the system description papers for more detail about how the monolingual data was used to initialize successful Unsupervised systems. For Unsupervised with Multilingual Transfer, the use of English-German bilingual corpora to initialize the Unsupervised system seems to have been highly effective, with a particularly strong result for the DE-HSB translation direction, perhaps due to a very strong starting point for the German encoder. For Very Low Resource, heavy usage of both types of transfer were made as well, with one particular focus being on efforts to leverage the similarity of Czech and Upper Sorbian using Czech/German parallel corpora.

The third trend was that another area of study for many systems was word segmentation (typically with a variant of BPE) and/or the use of morphological information, sometimes learned in translation at BPE or character level, sometimes monolingually. Finally the fourth trend was that there was also a significant focus on trying to make Czech more like Upper Sorbian using a variety of techniques, and/or sampling German data like Upper Sorbian data.

7 Conclusion

The WMT 2020 Shared Tasks in Unsupervised MT and Very Low Resource Supervised MT have created three interesting new benchmarks for future research. In addition to the initially proposed benchmark on straight-forward bilingual Unsupervised MT, we suggest the use of the Unsupervised Multilingual Transfer result as an additional new benchmark. The very low resource MT benchmark also generated strong participation from the research community.

We hope that additionally we have played a role in raising the interest of the NLP community in Upper Sorbian language processing, and that this interest will extend to Lower Sorbian language processing and in fact extend to working on other understudied languages as well.

We plan to organize similar tasks for the three benchmarks next year. Options include, e.g., more parallel data for Upper Sorbian, an Unsupervised Task for Lower Sorbian, and more ambitiously the inclusion of new typologically diverse languages. Please don't hesitate to contact us if you are interested, particularly if you have access to appropriate data.

8 Acknowledgments

This work has received funding from the European Research Council (ERC) under grant agreement No. 640550. Thanks very much to coorganizers: Hauke Bartels - Sorbian Institute, Olaf Langner - Witaj Sprachzentrum, Marcin Szczepanski - Sorbian Institute.

Cross-Lingual Transformers for Neural Automatic Post-Editing

Dongjun Lee
Bering Lab, Republic of Korea
djlee@beringlab.com

Abstract

In this paper, we describe the Bering Lab's submission to the WMT 2020 Shared Task on Automatic Post-Editing (APE). First, we propose a cross-lingual Transformer architecture that takes a concatenation of a source sentence and a machine-translated (MT) sentence as an input to generate the post-edited (PE) output. For further improvement, we mask incorrect or missing words in the PE output based on word-level quality estimation and then predict the actual word for each mask based on the fine-tuned cross-lingual language model (XLM-RoBERTa). Finally, to address the over-correction problem, we select the final output among the PE outputs and the original MT sentence based on a sentence-level quality estimation. When evaluated on the WMT 2020 English-German APE test dataset, our system improves the NMT output by −3.95 and +4.50 in terms of TER and BLEU, respectively.

1 Introduction

Automatic post-editing (APE) is the task of automatically correcting errors in the output of a machine translation (MT) system by learning from human corrections (Chatterjee et al., 2019). APE can be viewed as a cross-lingual sequence-to-sequence task, which takes a source sentence and the corresponding MT output as inputs and generates the post-edited (PE) output.

Our work is inspired by XLM-RoBERTa (XLM-R) (Conneau et al., 2019), a cross-lingual language model, which shows the state-of-the-art performance for a wide range of cross-lingual tasks. XLM-R takes a concatenation of two sentences in different languages as an input to generate cross-lingual representations. Similarly, we propose a Transformer (Vaswani et al., 2017) architecture for APE in which the encoder uses the same architecture as XLM-R.

In addition, we use XLM-R-based translation quality estimation (QE) (Lee, 2020) to further improve the PE output of the Transformer. QE is the task of estimating the quality of the MT output when only the source text is provided (Fonseca et al., 2019). We use two granularity levels of QE: word-level and sentence-level. Based on the word-level QE, we try to correct the wrong words or insert the missing words in the PE output. Through the sentence-level QE, we select the best translation among PE outputs and the original MT sentence to prevent over-correction (i.e., one of the APE models rephrases an already correct MT output).

Our contributions are summarized as follows:

- We propose a Transformer (Vaswani et al., 2017) architecture for APE in which an encoder takes concatenation of a source and MT sentence as an input to generate a cross-lingual representation and a decoder generates a PE output.
- We incorporate a word-level QE-based word masking. We replace `BAD` words with `<mask>` token or insert `<mask>` token for missing words in the PE output of the Transformer based on word-level QE.
- To predict the most probable word for each masked token, we use XLM-R (Conneau et al., 2019) that is fine-tuned using the translation language modeling (TLM) objective (Conneau and Lample, 2019).
- To address the over-correction problem, we introduce a sentence-level QE-based output selection. We select the sentence with the lowest predicted HTER among the MT and PE sentences as the final output.

In the experiment using the WMT 2020 English-German APE test set, our system achieves −3.95

Proceedings of the 5th Conference on Machine Translation (WMT), pages 772–776

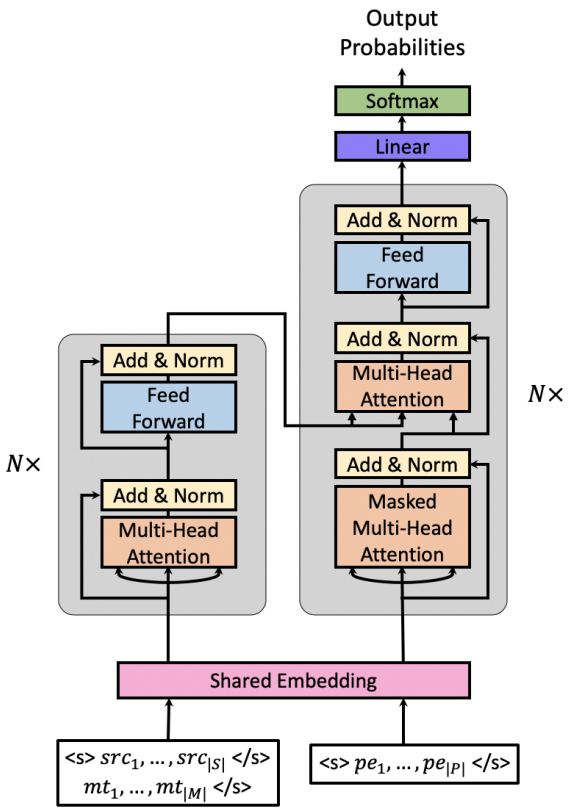

Figure 1: The cross-lingual Transformer architecture for APE.

TER and +4.50 BLEU improvement over the baseline (NMT output).

2 Methodology

Our approach for APE comprises three components: 1) a cross-lingual Transformer, 2) word masking based on word-level quality estimation (QE) and XLM-R-based mask prediction, and 3) output selection based on sentence-level QE.

2.1 Cross-Lingual Transformer for APE

As the first step of APE, we propose a cross-lingual Transformer (Vaswani et al., 2017) architecture that takes the concatenation of a source and MT sentence as a single input and generates a post-edited (PE) sentence, as illustrated in Figure 1.

A source sentence and its corresponding MT sentence are tokenized based on the same BPE model (Sennrich et al., 2016) that is trained using shared vocabulary of English and German. The input of the Transformer is a concatenated sequence of source tokens and MT tokens along with special tokens (<s>, </s>) as follows:

<s> src_1, ..., $src_{|S|}$ </s> mt_1, ..., $mt_{|M|}$ </s>

The output of the Transformer is a sequence of PE tokens that is also tokenized based on the same BPE model. Since the input and output use the shared dictionary, we tie the weights of the encoder word embedding layer, decoder word embedding layer, and decoder output layer. The rest of the model architecture follows that of Vaswani et al. (2017).

2.2 Word-level QE-based Word Masking and XLM-R-based Mask Prediction

We further improve the APE performance based on the word-level quality estimation (QE) (Fonseca et al., 2019) and XLM-R-based mask prediction (Conneau et al., 2019).

Word-QE-based Masking We use the word-level QE to predict if a word in the MT sentence is OK or BAD and if there are any missing words. We replace the words predicted as BAD with the <mask> token and insert the <mask> token where the missing words are predicted to exist. For the word-level QE, we use the same model architecture and hyperparameters from Lee (2020) but with the probability threshold for BAD as 0.8 instead of 0.5 because masking the correct token may degrade APE performance.

XLM-R Fine-Tuning We fine-tune pre-trained XLM-R using a parallel corpus based on the translation language modeling (TLM) objective (Conneau and Lample, 2019). A source (English) and target (German) sentences are tokenized with the same BPE model (Sennrich et al., 2016), which is trained based on shared vocabulary. We concatenate source and target tokens with a separation token (</s>) and use it as an input of XLM-R. Then, we randomly mask 20% of the BPE tokens in the target sentences and train the model to correctly predict the masked tokens.

Mask Prediction We use the concatenated sequence of source tokens and masked MT tokens as the input to the fine-tuned XLM-R. To predict the corresponding word for each masked token, we follow the highest probability first strategy proposed by Lawrence et al. (2019). We replace the <mask> tokens iteratively, and in each step, the <mask> token predicting the word with the highest probability is replaced with the predicted word.

2.3 Sentence-level QE-based Output Selection

There are cases where the APE models can degrade translation quality owing to unnecessary corrections, known as the over-correction problem (Fonseca et al., 2019). To prevent this, we select the best translation among the MT sentence and output sentences from APE models based on a sentence-level QE.

Sentence-level QE aims to predict the human translation error rate (HTER) (Snover et al., 2006) of the MT sentence, which measures the required amount of human editing to fix the MT sentence. We use the XLM-R-based sentence-level QE model proposed by Lee (2020) to predict the HTER for each of 1) the MT sentence, 2) PE output sentence of the cross-lingual Transformer, and 3) PE output sentence of word-level QE-based mask prediction. Finally, we select the sentence with the lowest predicted HTER as the final PE output.

2.4 Data Augmentation

Supervised learning for APE requires triplets comprised of source sentences, machine-translated (MT) sentences, and human post-edited (PE) sentences. Since the cost involved in achieving PE sentences is significant, we use a parallel corpus including only source and target sentences to build artificial triplets following the ideas from Negri et al. (2018).

First, we split the parallel corpus into a training set and test set. We then train an NMT model with the training set and use the test set to generate artificial triplets. We generate MT sentences based on the trained NMT model and we use the target sentences of the parallel corpus as PE sentences. We repeat this process with different data splits to amass large quantities of artificial triplets. Finally, we oversample the human-labeled triplets and merge them with the artificially-generated triplets to build a final training dataset (Junczys-Dowmunt and Grundkiewicz, 2018).

3 Experiments

3.1 Experimental Setup

We evaluate our model with the WMT 2020 English-German APE dataset.[1] For the evaluation metrics, we use the translation error rate (TER) (Snover et al., 2006) and BLEU (Papineni et al., 2002).

To generate artificial triplets (§2.4), we use the English-German parallel corpus provided by the shared task that consists of 23,440,059 pairs. We use 90% of the pairs to train a Transformer (Vaswani et al., 2017) NMT model using OpenNMT-py (Klein et al., 2017) and the rest of the pairs to generate artificial triplets. As a result of running the process five times with different data splits, we achieve 11,720,029 artificial triplets.

As a final training dataset, we oversample the official English-German APE dataset that consists of 7000 triplets 50 times and merge them with artificial triplets. We use the final triplets to train the cross-lingual Transformer (§2.1) and source-PE pairs to train the XLM-R with a TLM objective (§2.2).

3.2 Model Configuration

For the cross-lingual Transformer, we follow most of the hyperparameters from the base model of Vaswani et al. (2017), but for 5 epochs with early stopping. For the ensembling, we train five models with different random seeds. For the word-level and sentence-level quality estimation, we follow the model architectures and hyperparameters from Lee (2020). For mask prediction, we fine-tune XLM-R-Large (Conneau et al., 2019) using the Adam optimizer (Kingma and Ba, 2014) with a learning rate of 5e-6, a batch size of 8 for 1 epoch, and a dropout (Hinton et al., 2012) rate of 0.1.

3.3 Experimental Result

Table 1 presents the result of the ablation analysis for the proposed methods without the ensemble on the dev set. First, our cross-lingual Transformer improves the MT output by -1.85 TER and $+2.33$ BLEU. Sentence-level QE-based output selection further improves the performance of -0.42 TER and $+0.29$ BLEU. This demonstrates that our sentence-level QE-based output selection is effective for addressing the over-correction problem. Alternatively, when we use the word-level QE-based mask prediction model instead of the cross-lingual Transformer, the TER and BLEU are improved over the baseline by -1.10 and $+0.62$, respectively. This result shows that our word-masking and mask prediction models also significantly improve the translation quality. When we add the mask prediction model after the cross-lingual Transformer, the TER is improved by -0.27, but the BLEU slightly

decreased (-0.19). Finally, through the ensemble, we achieve an additional performance gain of -0.36 and $+1.02$ for the TER and BLEU, respectively.

Table 2 presents the official result evaluated on the WMT 2020 English-German APE test set. Our primary system contains all of the proposed methods, whereas the contrastive system does not contain word-level QE-based mask prediction. As can be seen, our primary system outperformed the contrastive system in terms of both TER and BLEU. In addition, our primary system achieves -3.95 TER and $+4.50$ BLEU improvement over the NMT output.

4 Conclusion

In this paper, the Bering Lab's submission to the WMT 2020 English-German APE shared task is described. A cross-lingual Transformer architecture is proposed for APE in which a single encoder takes the concatenation of a source and a MT sentences as an input to generate intermediary cross-lingual representations, and then a decoder outputs post-edited results. In addition, methods to improve the APE performance through translation QE are proposed. First, the incorrect or missing words in the post-edited output are masked based on a word-level QE. Then, the actual word for each mask is predicted based on the fine-tuned XLM-R using the translation language modeling (TLM) objective. Finally, a sentence-level QE-based output selection method is proposed to prevent over-correction. The experimental results show that our APE system significantly improves the NMT output in terms of both TER and BLEU.

Abstract

This paper describes POSTECH-ETRI's submission to WMT2020 for the shared task on automatic post-editing (APE) for 2 language pairs: English–German (En–De) and English–Chinese (En–Zh). We propose APE systems based on a cross-lingual language model, which jointly adopts translation language modeling (TLM) and masked language modeling (MLM) training objectives in the pre-training stage; the APE models then utilize jointly learned language representations between the source language and the target language. In addition, we created 19 million new sythetic triplets as additional training data for our final ensemble model. According to experimental results on the WMT2020 APE development data set, our models showed an improvement over the baseline by TER of -3.58 and a BLEU score of $+5.3$ for the En–De subtask; and TER of -5.29 and a BLEU score of $+7.32$ for the En–Zh subtask.

1 Introduction

Automatic post-editing (APE) is a subtask of MT, which aims to improve MT outputs by directly modifying machine-translated sentences (Chatterjee et al., 2019). Using APE systems to correct such errors that are automatically detectable can greatly reduce human effort compared to correcting machine-translated sentences manually from scratch (Pal et al., 2016).

Given that neural-network systems require a large quantity of training data, creating APE triplets, which each consist of a source sentence (`src`), a machine-translated sentence (`mt`), and a manually post-edited sentence (`pe`), requires a lot of human labor. Furthermore, because neural APE is a recently minted field of study, only a few small-sized training data sets are available at present. To mitigate such data shortage, several methods are proposed such that 1) create artificial APE triplets (Junczys-Dowmunt and Grundkiewicz, 2016; Negri et al., 2018); and 2) apply 'transfer learning' (Correia and Martins, 2019; Lopes et al., 2019). We believe that pre-trained models such as ELMo (Peters et al., 2018), OpenAI GPT (Radford et al., 2018), and BERT (Devlin et al., 2019) helped APE models learn rich language representations that compensated for the performance loss caused by using an insufficient quantity of training data.

APE is a task that handles both `src` and `mt` simultaneously, and learning a joint representation of these two inputs requires an understanding of both languages. Although previous works that used BERT have shown that transfer learning is effective in APE (Correia and Martins, 2019; Lopes et al., 2019), adopting BERT as a pre-trained language model may restrict to properly model the relation between two different languages because BERT is trained only on monolingual data sets. Therefore, following the recent trend of adopting transfer learning to various NLP tasks, we propose a new method that adopts a cross-lingual language model as a pre-trained langauge model for APE.

2 Related Work

2.1 APE models using BERT-based Encoder-Decoder

Lopes et al. (2019) proposed an APE system to which transfer learning is applied; the system uses multilingual BERT (Devlin et al., 2019) as its pre-trained language model in a Transformer encoder-decoder structure. They also introduced "conservativeness penalty", which discourages the APE system from frequently editing `mt`, into the system. In addition to using BERT as a cross-lingual encoder, they followed Correia and Martins (2019), which used pre-trained BERT to initialize weights of both the encoder and decoder, and shared weights of the

Proceedings of the 5th Conference on Machine Translation (WMT), pages 777–782

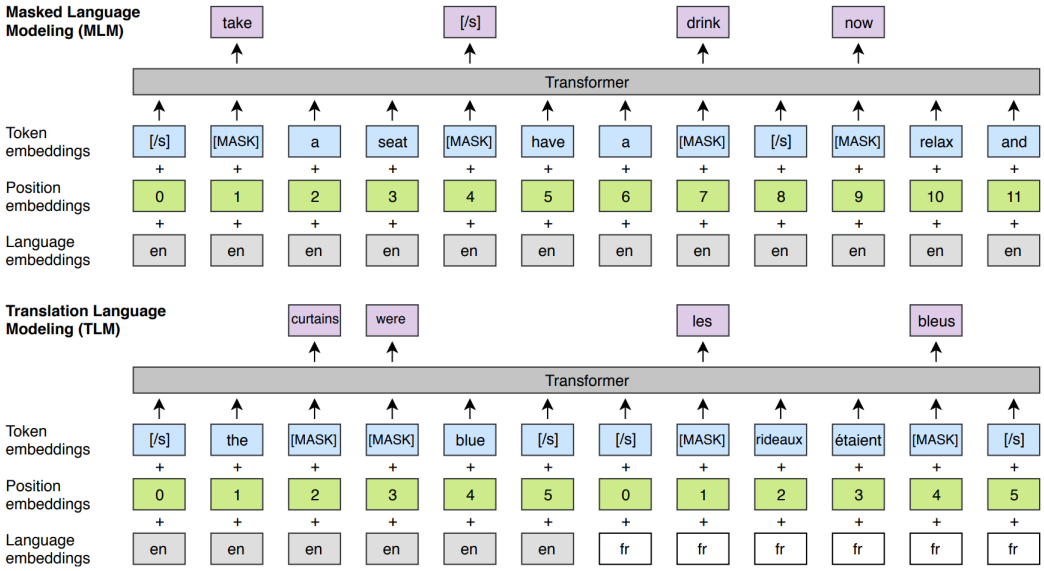

Figure 1: A comparison of the MLM objective and the TLM objective, taken from Conneau and Lample (2019)

self-attention layers both in the encoder and in the decoder.

Furthermore, they used a single encoder that accepts the concatenation of `src` and `mt` as input. To distinguish between the languages, they assigned different segment-embeddings for each language. This BERT-based encoder-decoder system showed the best performance for the English–German (En–De) language pair among all submissions for the WMT2019 APE shared task, proving the effectiveness of transfer learning.

2.2 XLM

After BERT had proposed masked language modeling (MLM), which requires monolingual data only (Devlin et al., 2019), Conneau and Lample (2019) introduced translation language modeling (TLM), which is an extension of MLM and allows the model to use parallel corpora as its input in the pre-training stage; the model can mask any token regardless of its language, and constructs its embedding by considering both sides of the context (Figure 1). The model learns through this process a cross-lingual representation during the training phase.

Considering that the APE task is a cross-lingual task, we expect that learning a cross-lingual representation of two different languages at the pre-training stage will be effective also in APE. Thus, we built a cross-lingual language model, which directly learns the joint representation of the two languages while being trained for the TLM objective, and we supplied it to our system. We describe our proposed model's architecture in the next section.

3 Model Description

Our APE system is built on top of Transformer's encoder-decoder structure (Vaswani et al., 2017). In the following subsections, we describe the main features of the encoder and decoder, respectively. Figure 2 illustrates the overall structure of our model.

3.1 Encoder

Transfer Learning. We built a cross-lingual language model and adopted this pre-trained language model to the encoder. It contains bidirectional and cross-lingual representations of the source and target languages, which are learned from predicting masked tokens from a big quantity of parallel data. Although a MLM+TLM model that was trained in 15 languages has been already released on the XLM GitHub page[1], to use a model that is trained with specific language pair corresponding to `src` and `mt` only, we built new MLM+TLM models. For En–De, we trained our model with the TLM objective on the pre-trained En–De MLM model which is released on the XLM Github page. For En–Zh, we trained our model with both the MLM and TLM objectives from scratch.

[1] https://github.com/facebookresearch/XLM

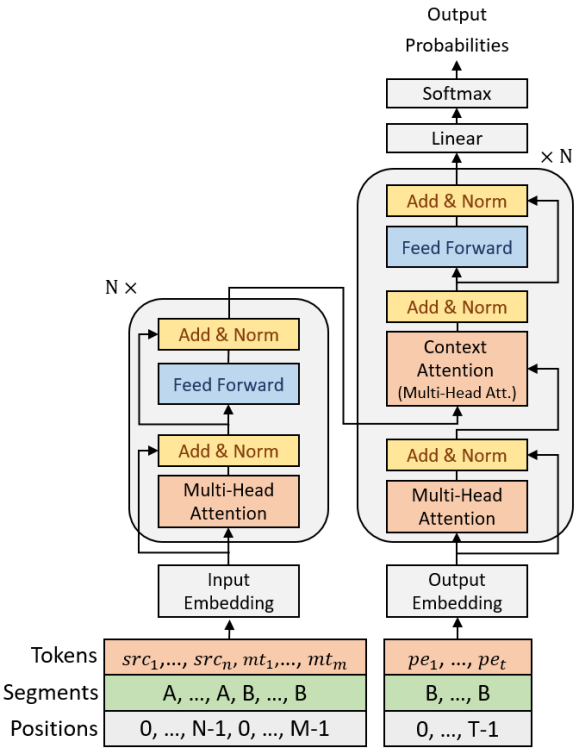

Figure 2: The architecture of our proposed APE model

Input representation. Unlike APE models that use a multi-source encoder that encodes `src` and `mt` separately (Junczys-Dowmunt and Grundkiewicz, 2018; Lee et al., 2019), we followed Lopes et al. (2019) so that the concatenation of `src` and `mt` was fed in to a single encoder. To distinguish one language from the other, we assigned different segment-embeddings to `src` and `mt`, respectively, and we also assigned individual positional-embeddings to `src` and `mt`.

3.2 Decoder

Because our pre-trained language model does not have a decoder, between two options, either randomly initializing the decoder or using another set of pre-trained weights, we chose the former; in contrast to Correia and Martins (2019), who made the encoder's self-attention weights be shared with the decoder, we randomly initialized the context attention layers and did not make the encoder and decoder share their parameters. To compensate for resulting variations in performance, we made an ensemble model of three to four individual models that have identical structures.

Table 1: The list of data sets we used to train TLM in the pre-training stage for the En–De & En–Zh language pairs. All data sets were filtered to contain only such sentences with a length between 3 and 70 tokens.

4 Experiments

4.1 Dataset

We applied Byte-Pair Encoding (Sennrich et al., 2016) to all the corpora in both the source and target language. We used the En–De shared sub-word vocabulary that is released on XLM GitHub, but we compiled an En–Zh shared vocabulary by using Wikipedia's dump files in English and Chinese. As in the WMT2020 official data, all English and German data sets were truncated and tokenized with Moses (Koehn et al., 2007) scripts, and the Chinese data set was tokenized with the Jieba tokenizer.[2]

4.1.1 Pre-training stage

We collected parallel corpora from the WMT2020 News Translation Task website,[3] OPUS,[4] and the WMT2019 Quality Estimation website.[5] Table 1 shows the list of parallel corpora that we used to pre-train our models for the two language pairs. To build a pre-trained language model for En–Zh, we built a MLM+TLM model from scratch because we did not have available MLM models that are trained only on the English and Chinese data. Whereas we trained TLM on the whole parallel corpora, we trained MLM only using each side of the parallel corpora as monolingual data. For En–De, we trained only TLM; we used the En-De pre-trained MLM model that is released on the XLM Github page. The sizes of the final parallel corpora that we used in the pre-training stage are 51.7M triplets for En–De and 43.8M for En-Zh.

Table 2: TER and BLEU scores for En–De and En–Zh language pairs. APE results for the WMT2020 test data will be provided by the shared task organizers. 'Single' is the model which showed the best performance among all the models that later became constituents of the ensemble model.

4.1.2 APE training stage

We used the WMT2018 and WMT2020 official APE data sets for En–De, and the WMT2020 official APE data sets for En–Zh. As supplementary training data, we created new synthetic triplets by following the method to make the eSCAPE NMT data set (Negri et al., 2018); we used the parallel corpora that are released as additional resources for the WMT2020 Quality Estimation task.[6] To create those triplets, we first reused each side of the parallel corpora as `src` and `pe`. We then applied the QE NMT model (Fomicheva et al., 2020)[7] to `src` and then used the resulting translations as `mt`. As a result, we obtained 19M new synthetic triplets for both En–De and En–Zh.

4.2 Training Details

We modified Facebook's XLM implementation that is released on Github[8] to adapt it for the APE task. Most hyperparameters such as the number of layers, the hidden size, and the number of attention heads, were set to those that XLM used for the MT task (Conneau and Lample, 2019). We then used different optimizer-settings for the pre-training and APE training stage, respectively. We used the Adam optimizer (Kingma and Ba, 2014) with a learning rate of 5×10^{-5} in the pre-training stage, and 1×10^{-4}, $\beta_1 = 0.9$, $\beta_2 = 0.999$, $\epsilon = 1 \times 10^{-6}$ in the APE training. We used 30k warm-up steps and a batch size of 32.

Similar to Lee et al. (2019), we divided the APE training process into two parts. The first is to train the model with 19M triplets, consisting of the 15-times up-sampled WMT official training data and our new synthetic data; we also added the WMT2018 official training data without up-sampling only for En-De. This first part took about three days on a single Tesla V100 GPU. The second is to fine-tune the model using only 7k triplets, which are official WMT2020 APE data. This second part took about three hours on the same GPU.

In the decoding stage, we used beam decoding with a beam size of five. We randomly initialized the weights of decoder's context attention layers and experimented our models four times to form an ensemble model of those four models. Our primary model is an ensemble model of three models, excluding one model that scored worst in terms of TER; this model showed the best performance on the WMT2020 development data set. Our contrastive model (Top4Ens) is an ensemble model of all the four models.

4.3 Results

We evaluated our results by comparing them to the MT baseline, which is uncorrected outputs of MT system. We used two evaluation methods that the WMT2020 APE task organizers suggested: Translation Error Rate (TER) and Bilingual Evaluation Understudy (BLEU). We used tercom software[9] to measure TER and a script of XLM GitHub to measure BLEU.

Table 2 describes the results of our proposed model on the WMT2020 official development and test data sets. For the development data set, our 'single' model outperformed the MT baseline in both language pairs. This result implies that our model successfully enhances the original quality of `mt`. Moreover, our primary ensemble model (Top3Ens) showed improvements over the MT baseline: for En–De by TER of -3.58 and by a BLEU score of

[6] http://www.statmt.org/wmt20/quality-estimation-task.html

[7] https://github.com/facebookresearch/mlqe/tree/master/nmt_models

[8] https://github.com/facebookresearch/XLM

[9] http://www.cs.umd.edu/ snover/tercom/

+5.3 and for En–Zh by TER of −5.29 and a BLEU score of +7.32.

Especially, for the test data set, our contrastive ensemble model showed a significant improvement for En–De by TER of −4.54 and a BLEU score of +6.16. For En–Zh, our primary submission showed an improvement over the MT baseline by a big margin: TER of −4.57 and a BLEU score of +5.78.

Although we submitted Top3Ens as our primary model, Top4Ens showed better TER and BLEU scores on the En–De test data set. We speculate that this result may have been caused by generality problem in which certain differences between the WMT2020 development and test data sets could occur.

5 Conclusion

For the WMT2020 APE shared task, we propose APE systems that adopt cross-lingual pre-trained language models. To better apply transfer learning to the APE task, we trained TLM in addition to using the original MLM models and initialized the decoder's weights in the same way as the encoder. Furthermore, we created new synthetic triplets to augment the training data and used the ensemble technique to build our final model.

Experimental results show that our proposed model achieved significant improvements on the WMT2020 development and test data sets in terms of TER and BLEU scores for both En–De and En–Zh language pairs.

Abstract

This paper describes POSTECH's submission to WMT20 for the shared task on Automatic Post-Editing (APE). Our focus is on increasing the quantity of available APE data to overcome the shortage of human-crafted training data. In our experiment, we implemented a noising module that simulates four types of post-editing errors, and we introduced this module into a Transformer-based multi-source APE model. Our noising module implants errors into texts on the target side of parallel corpora during the training phase to make synthetic MT outputs, increasing the entire number of training samples. We also generated additional training data using the parallel corpora and NMT model that were released for the Quality Estimation task, and we used these data to train our APE model. Experimental results on the WMT20 English-German APE data set show improvements over the baseline in terms of both the TER and BLEU scores: our primary submission achieved an improvement of -3.15 TER and +4.01 BLEU, and our contrastive submission achieved an improvement of -3.34 TER and +4.30 BLEU.

1 Introduction

There has been a surge of interest in developing Automatic Post-Editing (APE) models, which is capable of automatically correcting errors produced by a machine-translation (MT) system, and thus is an attractive way to improve the quality of the MT output. Currently, sequence-to-sequence modeling has become a dominant approach to constructing APE models (Chatterjee et al., 2019, 2018), which requires a large quantity of training samples. However, APE data[1] — comprising triplets of three texts: source (*src*), a machine-translation (*mt*) of *src*, and a human-crafted post-edited sentence (*pe*) of *mt* — is too small and costly to acquire. Consequently, the lack of APE data becomes a great obstacle to a satisfactory performance of sequence-to-sequence models.

To reduce such data scarcity, there have been several attempts at constructing synthetic APE data (Negri et al., 2018; Junczys-Dowmunt and Grundkiewicz, 2016). Most notably, Negri et al. (2018) proposed a simple but effective way to construct a large-scale synthetic APE data set eSCAPE (*src*, *mt*, *ref*), of which *src* and *ref* is the source and target text of freely available parallel corpora, respectively, and *mt* is a translation of *src* produced by the MT system that had been trained on those parallel corpora.

As eSCAPE has shown to be beneficial in training APE models (Chatterjee et al., 2019), it has become feasible to train deep APE models and also what most recent works have been relying on so far. Nevertheless, the availability of a limited quantity of parallel corpora may not only be insufficient, but also vary depending on the language pair, that is, while some language pairs have plenty of resources, some others have relatively few resources. We thus argue that further works to supply additional resources should be needed to mitigate the potential data scarcity.

In this work, we introduce a noising scheme by which corrupted texts (ref_{noise}) are produced from *ref* of parallel corpora, resulting in additional APE triplets (src, ref_{noise}, ref), where *src* and *ref* is the source and target text of parallel corpora, respectively. During post-editing, certain editing operations including the word insertion, deletion, substitution, and shifting are applied to translated texts (noisy texts) for error correction. Thus, we applied such operations to target texts (clean texts) of parallel corpora to inject errors in reverse. Moreover, to simulate the quantity of errors that the target MT system produces, we refer to the distribution of "Translation Error Rate" (TER) (Snover et al., 2006) occurring in the actual APE data to determine the quantity of errors to be injected.

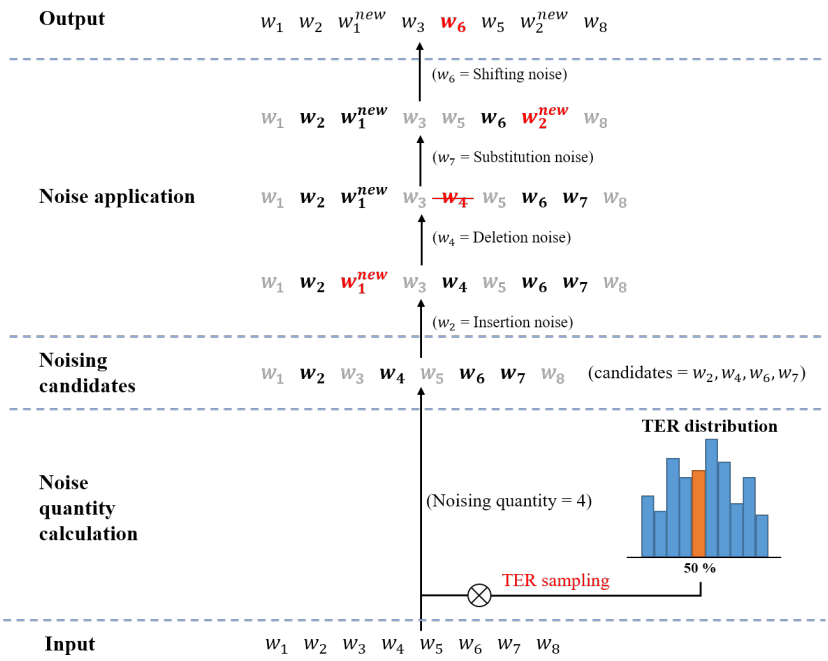

Figure 1: An illustration of the noising procedure

While we trained our models using the noising module, we supplied to the models synthetic APE data in addition to the WMT'20 APE data set as training data. The synthetic data was produced by using the eSCAPE method, which uses parallel corpora and a trained NMT model. We observed that models with noising module improved up to about -0.7 TER and +1.45 BLEU on the English-German (EN-DE) WMT'20 APE validation set compared to models without noising. Finally, our primary and contrastive submission to the WMT'20 APE shared task respectively recorded 28.41 TER and 54.22 BLEU, and 28.22 TER and 54.51 BLEU on the blind EN-DE WMT'20 APE test set.

2 Related Work

Noise injection to input sentences has become a popular method to let auto-encoders (Hill et al., 2016; Vincent et al., 2008) or pre-trained language models (Lewis et al., 2019; Devlin et al., 2019) learn how to reconstruct the original input. Because post-editing is a process of reconstructing corrupted translations, simulating corrupted MT outputs by injecting noise to the target sentence is a way to get synthetic APE training samples.

In the APE task, Xu et al. (2019) employed a data noising technique that incorporates a noise vector generated from a Gaussian or uniform distribution into the word embedding vector. However, their noising process has an effect on all tokens in a sequence, whereas only certain tokens in a given MT output are to be corrected in the APE process.

3 Method

3.1 Post-Editing Noise

Post-editing of *mt* texts requires four editing operations: insertion, deletion, substitution, and shifting. In other words, *mt* texts contain the following types of errors (The examples on the left side and right side are *mt* and *pe*, respectively.):

- Insertion operation implies that *mt* includes **deletion** errors:
  `We _ the world` → `We are the world`
- Deletion operation implies that *mt* includes **insertion** errors:
  `We are in the world` → `we are the world`
- Substitution operation implies that *mt* includes **substitution** errors:
  `We is the world` → `we are the world`
- Shifting operation implies that *mt* includes **shifting** errors:
  `We the world are` → `we are the world`

Considering the characteristics of editing operations, applying these operations to a clean text can simulate a corrupted *mt* text that can be post-edited to the original text. Thus, we corrupted a portion of words in a target text of parallel corpora, yielding a

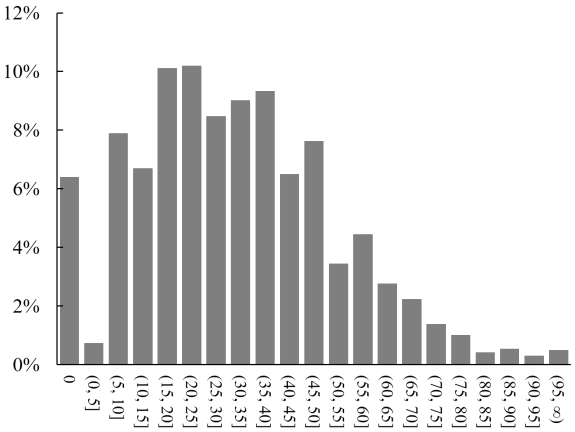

Figure 2: The categorical TER distribution of the WMT'20 training data, representing the proportion y [%] of samples belong to a specific TER range x.

new synthetic *mt* text which form a new synthetic triplet together with the corresponding source and target text in the parallel corpora.

3.2 Noising Procedure

Given an input sentence, we consider a noising procedure (Figure 1) (1) that specifies the quantity of words to become noise; (2) that selects specific words that will become noise according to the specified quantity; (3) and that determines the types of noise to be injected into the selected words.

Noising Quantity and Candidate Selection

The first step is to specify the quantity of words that will become noise in a given input sentence. Choosing a static proportion can be one option (Devlin et al., 2019), but imitating the proportion of errors that the target MT system produces would be more helpful to simulate the original *mt* text, considering that APE aims to correct the output produced by a particular MT system.

Accordingly, we refer to TER scores between *mt* and *pe* of the WMT'20 train set, which indicate the proportion of errors in *mt* that need to be corrected. Specifically, a TER range (e.g. $(45, 50]$) is drawn from the TER distribution in intervals of 5 (Figure 2), and then a specific value (e.g. 48) uniformly sampled from that range will be used as the error rate (e.g. $48 \rightarrow 0.48$). Finally, the noising quantity is calculated by multiplying the error rate by the input length. After specifying the noising quantity, we randomly select noising candidates among words in a given sentence according to the specified quantity.

Noise Application

Once the noising candidates have been selected, we now need to determine the types of noise that will be assigned to each candidate, and this process relies entirely on randomness. In particular, we produce four random numbers, making their summation equal to the noising quantity, and then this numbers are used as the quantity for each of the 'insertion', 'deletion', 'substitution', and 'shifting' post-editing noise. According to the quantity of each noising type, each type of noise is applied to words that are randomly selected among the noising candidates. Here, we present an example scenario as follows:

- Suppose that the noising quantity is 5 and the noising candidates are $w_1, w_4, w_7, w_9, w_{11}$ where w_i represents an input word in the i-th position.
- Given that the randomly selected numbers are $\{1, 2, 0, 2\}$, according to each of these four selected numbers, the words are randomly selected among the noising candidates, forming four subsets of selected words. (e.g.: $\{\{w_4\}, \{w_1, w_9\}, \{\emptyset\}, \{w_7, w_{11}\}\}$).
- Finally, one corresponding noise operation is applied to each subset of selected words. e.g.: $\{w_4\}$: insertion noise, $\{w_1, w_9\}$: deletion noise, $\{\emptyset\}$: substitution noise, $\{w_7, w_{11}\}$: shifting noise.

4 Experiment

4.1 Setup

Data. We collected publicly available parallel corpora that are listed on the WMT'20 Quality Estimation (QE) task webpage[2], which had been used to train the MT system by which *mt* texts of the WMT'20 QE corpus had been produced, and then we generated about 20M synthetic APE triplets (*src*, *mt*, *ref*) in the same manner as the eSCAPE method by using the pretrained MT system[3] that has been released on the QE task webpage. This synthetic APE triplets were used together with the official APE train set to train our APE model and a BPE model[4] by which we obtained a shared vocabulary of 32K subwords. During the training phase, the collected parallel corpora were used to

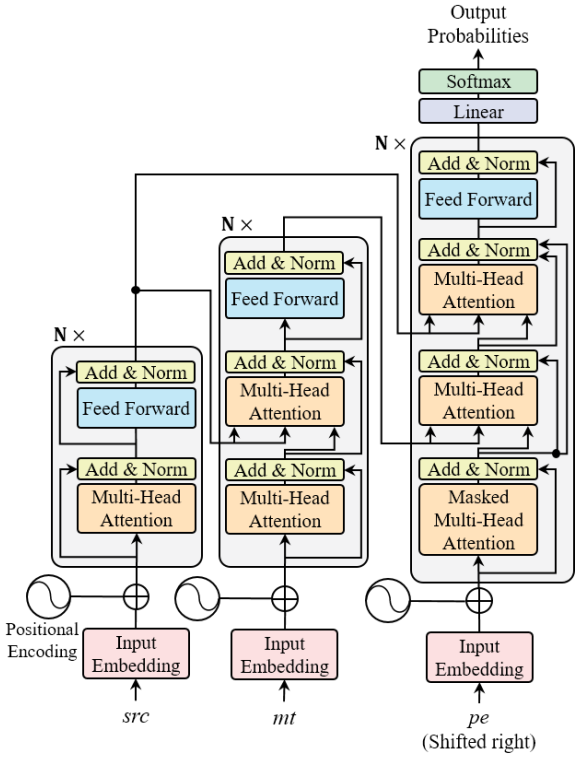

Figure 3: The structure of our APE model.

generate another synthetic APE triplets produced by our noising approach.

Model configuration. We adopted the "sequential APE model" proposed by Lee et al. (2019) to construct our APE model (Figure 3) by applying some minor modifications: the ReLU activation (Nair and Hinton, 2010) in the 'feed-forward' layers was replaced with the GELU activation (Hendrycks and Gimpel, 2016), an additional residual connection between the outputs of the first and third multi-head attention layer was added in the decoder. Additionally, we removed some details such as "stack-level attention" and "future masking to *mt*". We set our model's hyperparameters as follows: the size of the word embedding and all hidden dimensions at 768; the size of the inner dimension of feed-forward layers at 3072; 8 heads; 6 layers; and dropout rate at 0.1. The model was optimized using Adam (Kingma and Ba, 2015) with $\beta_1 = 0.9, \beta_2 = 0.998$, and $\epsilon = 1e^{-8}$, and we used the same learning rate scheduling as Vaswani et al. (2017) with 15,000 warmup steps. We implemented and trained our model by using the OpenNMT-py[5] framework.

APE_{base}	29.42	52.32	–	–
+Noise	28.72	53.77	–	–
Submission (Ensemble)				
Primary	28.70	53.77	28.41	54.22
Contrastive	–	–	28.22	54.51

Table 1: The evaluation results. APE_{base} stands for the model trained without using our noising approach.

4.2 Training Details

Training procedure. Training of the APE model is composed of two steps. At the first step, both the synthetic triplets and WMT'20 training data are used to train the model. Every time each training batch is assigned to the model, 25% of the synthetic triplets (*src*, *mt*, *ref*) in the batch are replaced with another synthetic triplets (*src*, ref_{noise}, *ref*) by applying the noising procedure (§3.2) to each *ref*. We here set the batch size at 33,000 tokens. The following step is to fine-tune the model by only using the WMT'20 data, starting at the convergence point found in the first step. At this step, we set the batch size at 1,024 tokens.

Ensemble. We trained two ensemble models for submission. Our primary submission (TERNoise-Ops-Ens8) is an ensemble of eight runs. We first selected the top five runs, which had the lowest TER on the development set, for three individual weight initializations. To form the ensemble model, we then selected among them the top two runs, for each of four edit operations, that make corrections most frequently. Our contrastive submission (TERNoise-nFold-Ens8) is also an ensemble of eight runs. Aiming for generalization to unseen data, all runs were trained and validated in a 4-fold setting on a data set into which the training data and development data had been merged. Then we selected the top two runs for each fold to form the ensemble model.

4.3 Result

Table 1 presents our evaluation results. As the WMT20 test data is blind to users, we were not able to conduct an evaluation on the test data set, but we observed that applying our noising scheme improved the post-editing quality of the model on the development data set. As a result, our primary submission, which is an ensemble of models adopt-

ing the noising scheme, showed an improvement of -3.15 TER score and $+4.01$ BLEU score on the test data set. In addition, our contrastive submission, which is an ensemble of models trained on the separate training data set to seek generality performance on unseen data, showed better results than our primary submission, resulting in its high generalization capability to the unseen the WMT20 test data.

5 Conclusion

We propose a noising scheme to supply APE models with synthetic APE triplets during the training phase. Our noising scheme is designed based on the error types that are defined in the APE task, and the quantity of noise that are injected during the training phase are determined in consideration of the distribution of those error types in the official training data. According to the experimental results, applying our noising scheme to APE models showed an improvement of the post-editing quality in terms of both TER and the BLEU scores, which indicates that our noising scheme was effective in training APE models although there may be differences between the synthesized errors and the actual MT errors. Therefore, in future work, we will aim to reduce those gaps caused by our noising scheme.

Abstract

The goal of Automatic Post-Editing (APE) is basically to examine the automatic methods for correcting translation errors generated by an unknown machine translation (MT) system. This paper describes Alibaba's submissions to the WMT 2020 APE Shared Task for the English-German language pair. We design a two-stage training pipeline. First, a BERT-like cross-lingual language model is pre-trained by randomly masking target sentences alone. Then, an additional neural decoder on the top of the pre-trained model is jointly fine-tuned for the APE task. We also apply an imitation learning strategy to augment a reasonable amount of pseudo APE training data, potentially preventing the model to overfit on the limited real training data and boosting the performance on held-out data. To verify our proposed model and data augmentation, we examine our approach with the well-known benchmarking English-German dataset from the WMT 2017 APE task. The experiment results demonstrate that our system significantly outperforms all other baselines and achieves the state-of-the-art performance. The final results on the WMT 2020 test dataset show that our submission can achieve +5.56 BLEU and -4.57 TER with respect to the official MT baseline.

1 Introduction and Related Work

Even machines can approach and achieve parity with human translations (Hassan et al., 2018) empowered by a sequence-to-sequence fashion (Bahdanau et al., 2014; Vaswani et al., 2017), post-editing is still an important and necessary step in the translation process, especially in scenarios where extremely high-quality translation results are essentially required such as business legal documents, technical product guides, medicine instructions and so on. It is the process whereby humans amend machine-generated translation to achieve an acceptable final product. Translation crowdsourcing paradigm, computer assisted translation (CAT) thus comes into being as demanded, which includes a hybrid of machine translation and human post-editing to meet translation scenarios with different quality requirements accordingly for accuracy, clarity, fluency, and domain adaptation.

However, post-editing, while improving, that can match human understanding of meaning, nuance, tone, humor–the list goes on, it's often worth paying extra more. The time spent on translation mistake corrections by humans remains substantial to the extent (Läubli et al., 2013) so that it even occasionally offsets the efficiency gained from the neural machine translation (NMT) systems. In this paper, we explore automatic post-editing (APE) in a deep learning framework where a two-stage training pipeline is engaged. The goal of APE task is to examine automatic methods of correcting translation mistakes produced by a black-box machine translation engine to improve the MT results. Human efforts are correspondingly reduced in the later editing process (Läubli et al., 2013) if our APE system can approach human translations as much as possible.

Traditionally, APE is a supervised learning task, requiring sufficient training data in the triplet of source (SRC), machine translation (MT) and post editing (PE) that are usually expensively available. Due to the limited number of such APE data released officially in this year's APE tasks and the specific domain, Wikipedia, which is quite different from the previous years'(IT domain), we adopt an imitation learning to mine WMT corpora, eSCAPE (Negri et al., 2018), Opus Wikipedia corpus (Wołk and Marasek, 2014) and our own English-German corpus to augment APE training data. However, pseudo data strategy is far from enough to train the state-of-the-art APE system. Inspired by the

Proceedings of the 5th Conference on Machine Translation (WMT), pages 789–796
Online, November 19–20, 2020.

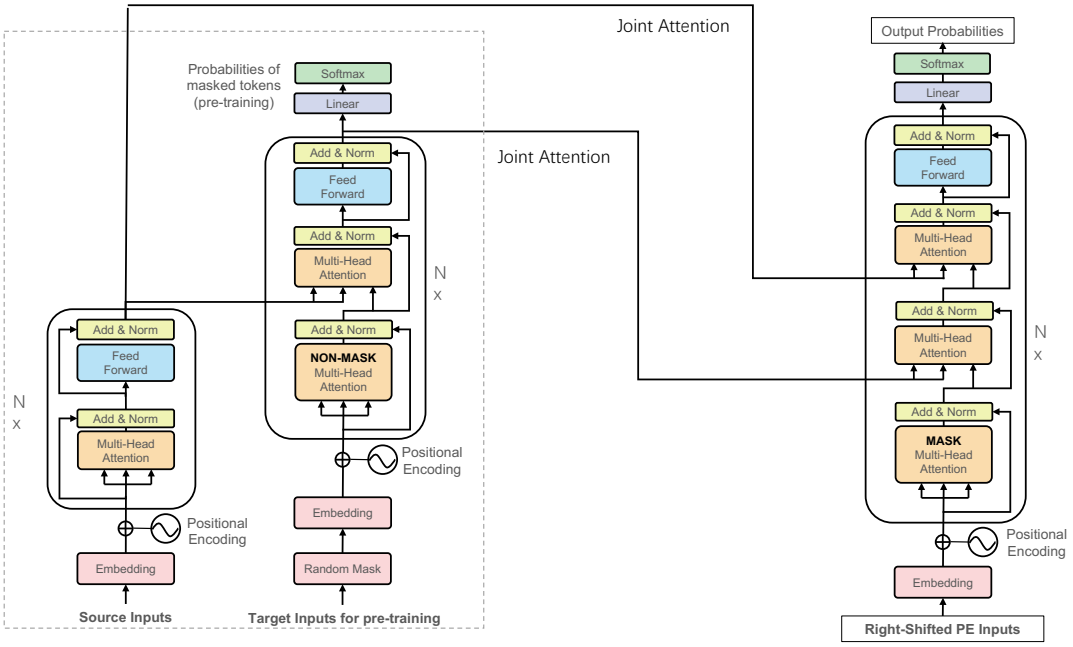

Figure 1: The APE model structure including detailed operations in pre-training and training

masked language model objective in the encoder BERT (Devlin et al., 2018), we introduce our Bert-like cross-lingual training objective to the encoder-decoder framework by adapting the decoder to become a memory encoder (Fan et al., 2019), allowing us to pre-train the target language model similar to BERT but conditioned on the source language text. Knowledge learned from the pre-training can be extensively transferred to many second-step downstream tasks, including but not limited to translation quality estimation, parallel corpus filtering and of course, automatic post-editing. The overall framework of our APE model is the same with the generative automatic post-editing model's structure in Wang et al. (2020).

Similar training mechanism is applied in the winner system of WMT 2019 APE Shared Task (Lopes et al., 2019), that wisely takes full advantage of the pre-trained multilingual BERT (mBERT) (Devlin et al., 2018) and achieves top performances.They concatenate the source and machine translation sentences to feed into the encoder mBERT and then fine tune the encoder and a transformer decoder where the context attention block is initialized by the self-attention weights of mBERT as well.

We examine our approach on the public English–German dataset from WMT 2017 APE shared task. Our system outperforms the top ranked methods in both BLEU (Papineni et al., 2002) and TER (Snover et al., 2006) metrics. For this year's WMT APE task, we finally submitted two ensemble English-German APE models according to different model selection methods and accomplish +5.56 increase in BLEU and -4.57 decline in TER on 2020 test set.

2 Methodology

In this section, we will introduce our APE model in terms of general structure and some computation details together with our data augmentation strategy.

2.1 APE Model Structure

The structure of our APE pre-training model originates from adapting the decoder in the transformer (Vaswani et al., 2017) to a memory encoder, following the exactly same design in Fan et al. (2019). We randomly pick 15% tokens in the target sentences during each training step to be substituted with a special [mask] token where predictions will be requisites accordingly, covering 12% masked, 1.5% substituted and 1.5% unchanged. In order to train a masked language model on the target sentences conditional on the sources, we accordingly remove the future mask matrix in the self-attention of the decoder to form a memory encoder, aiming to learn deep syntactic and alignment information of the ground truth. Therefore, during pre-training stage, the model is trained with high-quality English-German parallel corpora.

After we fully train the conditional language model on the target side, we apply an auto-regressive decoder on top of the pre-trained encoder-memory encoder model to decode the post-editing results in the stage of APE training by using the triplet data.

Figure 1 shows the details of our model structure. The part in the dotted line represents the pre-training stage with the removal of future mask in the memory encoder, and the whole picture describes the APE training process when the encoder-memory encoder pre-training model has been trained thoroughly. Note that the order of joint attentions of encoder and memory encoder with the decoder separately can be switched. Our experimental results in the following section illustrate this slight change can bring benefits to the diversity of the models and enhance the final ensemble's performance.

2.2 Data Strategies

High-quality parallel corpus filtering Our pre-training model requests high-quality parallel corpora. The dual conditional cross-entropy model (Junczys-Dowmunt, 2018) has been proven effective in WMT 2018 Corpus Filtering Shared Task. The cross-entropy scores according to two inverse translation models trained on clean data are used as the quality indicator so that we are able to mine qualified parallel sentences from noisy parallel corpora.

APE training data augmentation. Domain Adaption methods have been also investigated because of the small amount of official English-German APE training set and the special domain, Wikipedia. A semi-supervised CNN domain classification model (Chen and Huang, 2016) trained with in-domain seed and other general-domain data is utilized to extract in-domain source and target sentences from English-German corpora to augment pseudo sources and post-edits for APE training. To generate the corresponding machine translations of the classified in-domain source sentences, we use the rest of our corpus to train a neural machine translation model with model setting in Vaswani et al. (2017) to produce the MT results. The pseudo sources and post-edits are used as supplementary data during pre-training, and the pseudo triplets improve APE performance on the basis of only using official APE training set.

Algorithm 1 Imitation Learning for Fine-tuning

Require: Reference Set $\mathbf{R} = \{(s_i, m_i, e_i)\}_{i=1}^{M}$, Full Training Set $\mathbf{T} = \{(s_j, m_j, e_j)\}_{j=1}^{N}$, hyperparameters $K \in [1, +\infty)$, $\alpha \in (0, 1)$.

Set the output dataset $\mathbf{R} = \{\}$.
for each $(\mathbf{s_i}, \mathbf{m_i}, \mathbf{e_i})$ in R **do**
  $\vec{V_r} = (TER(e_i, m_i), Length(e_i))$
  Candidate Set $C = \{\}$
  for each $(\mathbf{s_j}, \mathbf{m_j}, \mathbf{e_j})$ in T **do**
    $\vec{V_t} = (TER(e_j, m_j), Length(e_j))$
    for m in 0,1 **do**
      if $\left\| (\vec{V_r}[m] - \vec{V_t}[m])/\vec{V_r}[m] \right\| > \alpha$ **then**
        Skip this training sample
      end if
    end for
    Add this training sample $(\mathbf{s_j}, \mathbf{m_j}, \mathbf{e_j})$ to C
  end for
  if size of $C > K$ **then**
    Sort candidates in C by its cosine similarity to $\vec{V_r}$
    Remain only the top K candidates in C
  end if
  for each candidate in C **do**
    Add it to F
    Remove it from T
  end for
end for
return Filtered Dataset F.

Imitation learning. To boost the APE model performance, we optimize our model during the APE training stage with further filtered APE data by an imitation learning method, since we noticed that there are gaps between the distributions of TERs in different types of our APE training set. Deeply motivated by Junczys-Dowmunt and Grundkiewicz (2016), we leverage the official training data containing real 7000 in-domain APE triplets as a reference set and apply Algorithm 1 to sample a subset of the whole training data in Table 1. Then we fine tune the APE model further with such a subset that has a similar distribution with this year's official training data. All the details of data usage will be described in the following experiment section.

3 Experiment

We conduct our experiments on two different datasets: First, to make a fair comparison with other top-ranked systems on WMT APE tasks in recent years, we perform a single model evaluation on the WMT 2017 English-German APE Shared Task without any other pseudo data except the Artificial dataset (Junczys-Dowmunt and Grundkiewicz, 2016) provided officially (for fair comparisons, and we avoid using the Escape Corpus (Negri et al., 2018) which has not been released until 2018); Second, we carry out a series of experiments

Real/Pseudo	MT Engine	In/Out Domain	Up-sample Weight	Description	Size
Real	SMT	Out-domain	10	Train set of WMT 16&17 APE task	23k
Real	NMT	Out-domain	20	Train set of WMT 18 APE task	13.4k
Real	NMT	In-domain	40	Train set of WMT 20 APE task	7k
Pseudo	SMT	Out-domain	1	Artificial Dataset	4.4M
Pseudo	NMT	Out-domain	1	Escape Corpus (NMT)	4.9M
Pseudo	NMT	In-domain	1	Our in-domain pseudo data	20M
Total	-	-	-	Final training set	30M

on the WMT 2020 English-German APE Shared Task with strategies including data argumentation, quality filtering, domain adaptation, and model ensemble to accomplish the overall performance of our model.

3.1 Setup

Dataset. For the experiments on WMT 2017 APE, we verify our APE model design on the open public WMT 2017 English-German APE Shared Task (Ondrej et al., 2017). The official training set consists of 23K real triplets (SRC, MT, PE) for training and another 2K triplets for testing from the Internet Technology (IT) domain. Besides, the shared task offers a large-scale artificial synthetic corpus containing around 500K high-quality and 4 million relatively low-quality synthetic triplets. We over sample the APE real data by 20 times and merge it with the synthetic data, resulting in roughly 5 million of triplets for both pre-training and APE training. The final APE system is selected based on WMT 2016 APE test set.

For the experiments on WMT 2020 APE, we use all available APE triplets of WMT English-German APE tasks released since 2016, including about 43.4K real triplets as well as 9.3M synthesized data made up with Artificial (Junczys-Dowmunt and Grundkiewicz, 2016) and Escape (Negri et al., 2018). Considering the application domain for this year's task changes from IT to Wikipedia and the size of the official in-domain training set is quite small (only 7000 samples), we generate about 20M in-domain pseudo data for our model training as follows:

1. We apply the cross-entropy scoring algorithm described in section 2.2 on our own English-German parallel corpus and filter out about 200 million high-quality parallel data with a proper threshold.

2. We collect the Wikipedia corpus from Wołk and Marasek (2014), which contains more than 2 million of English-German parallel sentences. We up-sample the SRC of this year's training data 20 times and mix them with the English side of Wikipedia corpus as our in-

domain seeds and train a domain classification model as described in section 2.2 with other general-domain data including the news and biomedical dataset from the WMT 2020 website. Afterwards, the domain classfication model is applied to extract about 20 million of in-domain parallel sentences from the 200M high-quality parallel data mentioned above.

3. The left 180 million are used to train a English-German transformer-based neural machine translation model (Vaswani et al., 2017) with the OpenNMT (Klein et al., 2017) source code. The sources and targets of the 20M high-quality in-domain parallel corpus are treated as SRCs and PEs and the decoding results from the trained NMT model are regarded as corresponding MTs. These in-domain pseudo triplets are mixed with all available training set from the WMT APE Shared Task since 2016 with differentiated up-sample weights as our final training set, as shown in Table 1.

Pre-processing. In all of our experiments, we apply truecasers trained independently for English and German seperately (Koehn et al., 2007) and process our data into subword units (Kudo, 2018) with a 32K shared vocabulary. Triplets with more than 70 subword units in any one of the SRCs, MTs or PEs are removed.

Evaluation Metrics. We mainly evaluate our systems with the metrics, translation edit rate (TER) (Snover et al., 2006) and bilingual evaluation understudy (BLEU) (Papineni et al., 2002), since they are standard and widely employed in evaluation of the WMT APE tasks.

Model Setting. All experiments are trained on 8 NVIDIA P100 GPUs for maximum 100,000 steps for about two days until convergence, with a total batch-size of 65536 tokens per step and the Adam optimizer (Kingma and Ba, 2014). Parameters are being tuned with 12,000 steps of learning rates warm-up (Vaswani et al., 2017). Except these modifications, we follow the default transformer-based configuration (Vaswani et al., 2017) for other hyper-parameters settings.

3.2 Results on WMT 2017 APE Shared Task

We verify the validity and efficiency of our proposed model on WMT 2017 APE test data since all of the winners of WMT APE Shared Tasks of recent years do report their results of single models on this dataset (Junczys-Dowmunt and Grundkiewicz, 2018; Correia and Martins, 2019). To make a fair comparison, we do not use any extra data for training as described in the data setup.

The main results of APE systems are presented in Table 2, demonstrating that our single model, even without pre-training, outperforms all winners of the WMT APE Shared Task from 2017 to 2019 on both BLEU and TER metrics.

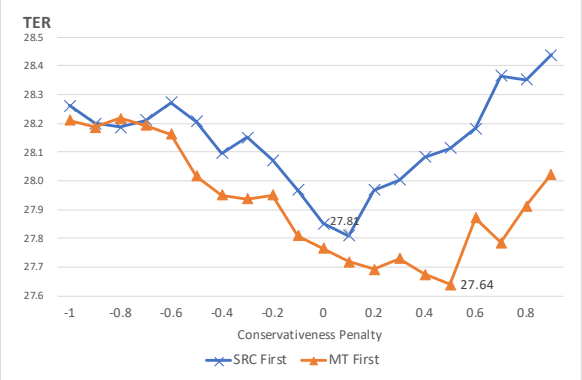

Figure 3: TERs on the English-German Development Set of WMT 2020 APE Shared Task from the Further Optimized Models with Different Values of Conservativeness Penalty

3.3 Results on WMT 2020 APE Shared Task

For this year's task, we adopt various of strategies including data augmentation, further optimization by imitation learning and model ensemble.

Data Augmentation As described in section 2.2, we utilize several algorithms, quality filtering and domain adaption, to construct our own in-domain pseudo data for APE training. We conduct experiments with and without in-domain pseudo data on two different model structures described in Section 2.1 for decoder joint attention switching (referred as SRC-First and MT-First respectively in the following discussion). Results on the 2020 development set in Figure 2 indicate that our data augmentation strategies can generate powerful pseudo data which significantly improve the model performance in this year's APE task.

Further Optimization via Imitation Learning The hyper-parameters α and K in Algorithm 1 are set to 0.3 and 500 according to empirical studies. Finally, around 2M triplets are filtered from the full training set via the imitation learning algorithm. We compare TERs before and after APE fine tun-

Model	BLEU↑	TER↓	Note

Our Ensemble×5	**56.06**	**26.99**	Our primary submission

Table 3: Main Results in the English-German Development Set of the WMT 2020 APE Shared Task

Model	BLEU↑	TER↓
Official Baseline	50.21	31.56
Our Primary Submission	55.58	27.03
Our Contrastive Submission	**55.77**	**26.99**

Table 4: Submission Results in the English-German Test Set of the WMT 2020 APE Shared Task

ing with the filtered data in Figure 4 with the two different model structures. It can be clearly shown that the APE model can be further improved.

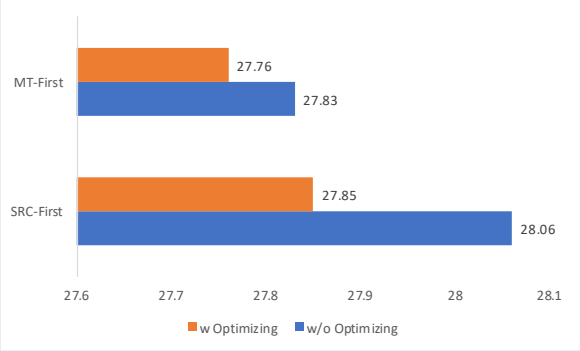

Figure 4: TERs on the English-German Development Set of WMT 2020 APE Shared Task for Different Model Structures with/without Further Optimizing

Ensemble We train the two different APE models (SRC-First & MT-First), each for three times with 30M APE training set to get 6 primary APE models and fine tune all of them with 2M filtered APE data via imitation learning for further optimization. Then, we obtain 12 APE models, 6 primary models and 6 optimized ones. Our final primary submission is an ensemble of the top 5 primary models with lowest TERs. In contrast, an ensemble of the top 5 optimized models is submitted as well for validation of imitation learning method.

Following the winning system of last year, we apply the conservativeness penalty (Lopes et al., 2019) on each model before ensemble. As shown in Figure 3, the local optimal solutions for the conservativeness penalty may be various among models. Therefore, instead of a fixed constant, we apply the most appropriate penalties for each model according to their performance on the 2020 development set. Results of our ensemble models in the development set and the test set can be found at Table 3 and Table 4 respectively.

Besides, we also train last year's winning system five times (BED (Lopes et al., 2019)) with the exactly same data we use for WMT 2020 APE task based on the source code they released[1] and pro-

[1]https://github.com/deep-spin/OpenNMT-APE

duce an ensemble result reported in Table 3. Evaluated on 2020 development set, both of our final ensemble model in primary and contrastive submissions outperform the winning system of 2019. The final results on the 2020 test set released officially show that our ensemble models significantly improve the machine translations with significant margins in TER and BLEU (-4.57 TER and +5.56 BLEU).

4 Conclusion

This paper describes our automatic post-editing system for the WMT 2020 English-German APE Shared Task. We introduce a cross-lingual Bert-like conditional model with an innovative memory encoder which can capture the deep semantic information of machine translations conditional on the source sentences. In addition, efforts on data augmentation strategies, corpus filtering and imitation learning, are able to overcome the scarcity of real APE data and further improve the model performance together with the ensemble strategy. Our single APE model outperforms all winner systems of recent years' WMT APE Shared Tasks on the WMT 2017 English-German test set and achieves impressive performances on the WMT 2020 English-German APE test set.

Abstract

The paper presents the submission by HW-TSC in the WMT 2020 Automatic Post Editing Shared Task. We participate in the English→German and English→Chinese language pairs. Our system is built based on the Transformer pre-trained on WMT 2019 and WMT 2020 News Translation corpora, and fine-tuned on the APE corpus. Bottleneck Adapter Layers are integrated into the model to prevent over-fitting. We further collect external translations as the augmented MT candidates to improve the performance. The experiment demonstrates that pre-trained NMT models are effective when fine-tuning with the APE corpus of a limited size, and the performance can be further improved with external MT augmentation. Our system achieves competitive results on both directions in the final evaluation.

1 Introduction

Automatic post editing (APE) has been used in many scenarios where the performance of a black-box Machine Translation (MT) system is unknown, or, domain specific corrections are required (Pal et al., 2016; Junczys-Dowmunt and Grundkiewicz, 2017; Correia and Martins, 2019; Chatterjee et al., 2020). The continuous improvements of NMT systems's performances along with deep learning advancements insert great challenges on developing sound APE systems, as simple translation errors are rarely seen in machine translation outputs nowadays while the remaining errors are still tough to solve. Transfer learning and data augmentation techniques have demonstrated their efficiency in recent years when models are trained on datasets with limited size (Devlin et al., 2018). Therefore, such techniques are also adopted in APE tasks (Lopes et al., 2019; Chatterjee et al., 2019).

Participants in the APE tasks are required develop systems to automatically post edit the translation outputs from an unknown MT system (Chatterjee et al., 2019). In this year, the dataset has changed in terms of domain (from IT to Wikipedia) and quality of MT (a significant decrease in BLEU). Using previous dataset or officially provided synthetic corpus (such as Artificial and eSCAPE) (Junczys-Dowmunt and Grundkiewicz, 2016; Negri et al., 2018) to enlarge the training set might not be appropriate under such circumstance due to the change in data distribution. Therefore, we decide to perform transfer learning with the officially released training set and integrate Bottleneck Adapter Layers (BAL) (Houlsby et al., 2019; Yang et al., 2020) to prevent over-fitting.

Our model is built based on Transformer (Vaswani et al., 2017) and is pre-trained on the WMT 2019 and 2020 news translation corpora. Compared with the work by (Lopes et al., 2019), we consider that it is more intuitive to use a pre-trained NMT model rather than a pre-trained multilingual language model (LM) (Devlin et al., 2018). During our experiment, we find that fine-tuning the model only on the officially released corpus could easily reach the performance ceiling. As a result, we wondered whether it is possible to introduce external translations as additional MT candidates for data augmentation so as to provide more diversified features. Fortunately, our experiment results demonstrate the effectiveness of such approach. The architecture of our model is shown in Figure 1.

The contributions of our work are as follows:

- We fine-tune the pre-trained NMT models on APE tasks, demonstrating the effectiveness of transfer learning.
- BAL is integrated into the model, further improving the training efficiency as well as the performance.
- Additional MT candidates are introduced to

Proceedings of the 5th Conference on Machine Translation (WMT), pages 797–802
Online, November 19–20, 2020.

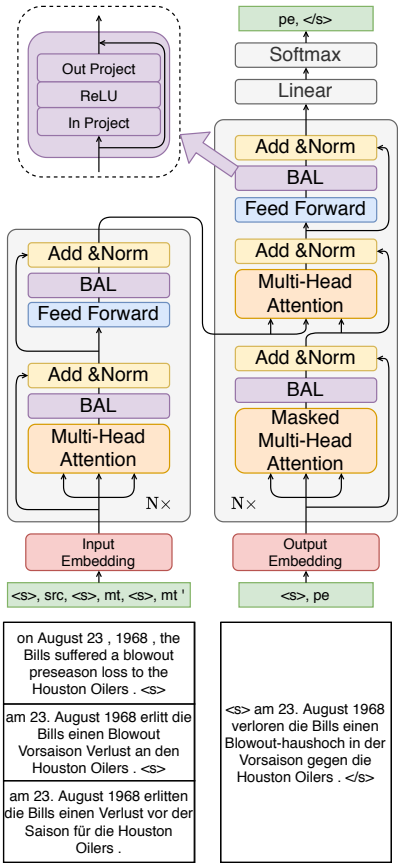

Figure 1: This figure shows the architecture of our model, where MT and augmented MT are concatenated with SRC for passing into the encoder, and PE are generated with the decoder. An example is also shown in the box below the architecture figure.

improve feature diversity, which also significantly improves the performance.

- A detailed case study on the dev set is conducted. We divide post-editing operations into three categories and 10 sub-categories based on their patterns, offering fine-grained suggestions for researchers to build APE models to deal with specific patterns.

2 Task

The dataset contains 7,000 sentences for the training set, 1,000 for the dev and 1,000 for the test. Note that it is also used for the WMT 2020 Word- and Sentence-level Quality Estimation (QE) shared task. Detailed statistics of the dataset is listed in Table 1, showing some metrics of the source (SRC) and translation (MT). From the BLEU (Papineni et al., 2002) scores we can see that the gaps between MTs and PEs are relatively large when compared with that in WMT 2019 (BLEU $>$ 70+).

Attributes	En-De	En-Zh
# Instance	7,000	7,000
# SRC Token	11,4980	115,585
# MT Token	112,342	120,015
% MT Token BAD	28.15	54.33
% MT Gap BAD	4.60	8.04
% SRC Token BAD	26.95	53.60
BLEU (MT, PE)	49.40	30.40
μ(HTER)	0.3181	0.6280
σ(HTER)	0.2017	0.2040

Table 1: The statistics of the training set for both language pairs.

From this aspect, we consider the task is easier this year because over correction will not be a serious problem. However, as the corpora size is much smaller than that of the previous year, this year's APE task is challenging in another way. The evaluation metrics used this year, TER (Snover et al., 2006) and BLEU (Papineni et al., 2002), are exactly the same as that of previous years.

3 Method

3.1 Model

As described in the previous section, due to the limited corpus size, our team decide to employ transfer learning in this task. However, unlike the method proposed in (Lopes et al., 2019), where a multilingual BERT is used as encoder and decoder, we use a pre-trained NMT model and regard it as a more intuitive approach.

We basically treat the APE task as an NMT alike problem, which takes source (SRC) and machine translations (MT) as input and generate PE autoregressively. To adapt this idea with Transformer, we simply concatenate the SRC and MT with the token $<$ s $>$. For models with shared vocabulary and embeddings such as our pre-trained En-De model, this strategy works fine. But for models without sharing input and output embedings such as our En-Zh model, we perform the concatenation with the hidden features after passing through the word embedding separately with the encoder and decoder input embeddings, but keeps the positional embedding normally used.

We perform experiments with this model on the 2019 and 2020 in-domain dataset and find two problems:

- The model converges fast (less than 4 epochs),

but starts over-fitting soon.

- The performance of the model is not good enough on the 2019 dataset, which means it might not be competitive on the 2020 evaluation.

3.2 Bottleneck Adapter Layer

Regarding the first problem, we decide to use the bottleneck adapter layer to reduce the model complexity by only updating the introduced adapter but keeping other parameters fixed. The bottleneck adapter is proposed by (Houlsby et al., 2019), which is similar to the FFN layer in the Transformer but with a low dimensional hidden layer for non-linear activation. In the experiment, we integrate the adapter layer after the self attention layer and the FFN layer for each block in both encoder and decoder. In addition, we find that expanding the hidden size of the neck to the double of the model's hidden size could make the model converge to lower dev loss comparing with using "thinner" or "thicker" necks (i.e. $1/2 \times$ d_model and $2 \times$ d_model). We suppose this size could restrain the complexity of the model at the most suitable level.

3.3 Augmentation with External MT

To further improve the performance, we start investigating the probabilities of adopting external resources for data augmentation. However, as mentioned in previous sections, the domain of eSCAPE (Negri et al., 2018) and the artificial (Junczys-Dowmunt and Grundkiewicz, 2016) corpora are different from that of this task. Afraid of introducing additional biases if incorporating such corpora, we choose to generate more MT candidates (denoted as MT') with the training set and let the model learn complementary information from each other.

More specifically, we first use an additional MT system to create the MT' from the provided SRC text. Then, we simply concatenate the MT' with the SRC and MT sequence to form the new sequence: [SRC, $<$ s $>$, MT, $<$ s $>$, MT$'$], then, use it same as before.

Intuitively, MT' with higher quality can be beneficial for the performance because it is closer to the PE when comparing with the official MT. Therefore, we translate the training set with different MT systems including NMT models trained by us and some publicly available online MT systems.

	En-De		En-Zh	
System	**BLEU**	**TER**	**BLEU**	**TER**
baseline	50.37	31.374	22.62	60.417
+ Fine-tuning	59.51	25.941	31.74	49.257
+ External MT	65.72	20.959	37.37	47.830
+ Ensemble	66.96	20.222	37.83	46.918
Submission	66.89	20.21	37.69	47.36

Table 2: The experimental result of two language pairs evaluated with BLEU and TER on the 2020 dev set, as well as the officially published submission result on the test set. Note that we ensemble 4 and 2 models for En-De and En-Zh, respectively.

Finally, we find that the translation from Google Translate has the best quality (in terms of BLEU for dev set, 67.8 for En-De and 41.77 for En-Zh), and thereby its outputs becomes our augmented MT.

4 Experiment

4.1 Experimental Settings

Our En-De model is implemented with fairseq (Ott et al., 2019) since their published model is pre-trained on WMT 2019 news translation dataset, with BLEU score of 42.7 in evaluation. Our En-Zh model is implemented with THUMT (Zhang et al., 2017) and trained for the WMT 2020 news translation task, which achieved a BLEU score of 46.0 in evaluation. The Transformer model used for both language pairs is Transformer-big with 6 encoders and 6 decoders, and the hidden size is 8192 for FFN layers and 1024 for all other layers.

Note that the vocabulary and encoder/decoder embeddings of the En-De model are shared between two languages and contains 42K of sub-tokens. The vocabulary of the En-Zh model is not shared, and contains 32K and 30K sub-tokens for En and Zh respectively. The BAL used in our model is also modified to have a larger parameter size, where the hidden size of the middle layer is set to 2048.

All models are trained on an Nvidia Tesla V100 GPU with 32G memory. We use the Adam (Kingma and Ba, 2015) optimizer with a constant learning rate of 1e-4 for optimization, and the batch size is 32. FP16 is also used to accelerate training. Models with BALs could converge in less than 8 epochs within 5 minutes.

Categories	Patterns	Num of samples	Proportion	
Knowledge Complement	Named Entity	448	20.38%	38.38%
	Transcreation	206	9.38%	
	Terminology	190	8.65%	
MT Error Correction	Typo	364	16.57%	43.84%
	Disfluency	293	13.34%	
	Illogical	148	6.74%	
	Punctuation Error	71	3.23%	
	Mis-Translation	71	3.23%	
	Over-Translation	16	0.73%	
Stylized Correction	Personal Preference	383	17.45%	17.45%

Table 3: Three categories with eleven types of PE patterns and their proportions, where the MT Error Correction takes the largest part, and are considered as most likely to be solved by APE models.

4.2 Experimental Results

Table 2 shows the experimental results evaluated on the 2020 dev set, where the baseline result is produced by directly calculating scores between the provided MT and PE.

The first experiment is performed by fine-tuning all parameters of the pre-trained Transformer on the official training set, which obtains 8+ of performance gains comparing with the baseline. This demonstrates that fine-tuning the pre-trained NMT model on the limited dataset can be useful.

The experiment of adding external MT for data augmentation shows significant improvements on the performance. However, after performing experiments with different MT candidates, we find that the quality of augmented MTs could influence the performance to a large extent, which motivates us to further improve the robustness of the model.

5 Analysis

Except from focusing on modelling and experimenting, we also conduct an in-depth analysis of the dataset by tagging the PE operations on the dev set. Based on the tags, we categorize PE operations into three categories and try to figure out which kind of PE operations can be learned by an APE system.

We analysis the En-Zh dev set and labeled totally 2196 PE operations, where each sentence has approximately 2.2 corrections. By categorizing these PE operations, we conclude three categories with 10 sub-categories, as described in Table 3. For the first category, SRC text often contains domain specific knowledge or implicit contexts, like Named Entities, terminologies. Strong background knowledge is required when a post-editor translate such text (Yang et al., 2020, 2019). The second category mainly deals with explicit grammar or semantic errors like typo, mis-translations or logical errors, mostly requiring only commonsense to correct. Modifications under the third category are mainly related to the editor's preferences, for example, the format of names and dates. Several examples of the three categories have been shown in the Table 4 in the Appendices.

By observing the output of our system, we find that the first and third categories are relatively difficult for the model to learn in an open domain setting, because of their complexity and uncertainty. For the second category, a pre-trained model has the prior learned from the massive bilingual text, and thereby can be easily fine-tuned to detect and make correction on these mistakes. We believe that further investigation can be performed to explore methods to improve the performance on specific patterns, which is also the research direction of our work.

6 Conclusion

This paper presents our work in the WMT 2020 APE shared task. We adopt transfer learning and data augmentation by fine-tuning a pre-trained Transformer on the provided dataset with external MTs. The experimental results demonstrate the effectiveness of our method. Meanwhile, we achieve competitive results on the test set in the evaluation. Apart from that, we also conducted an in-depth analysis on the dev set, and group the PE operations into several fine-grained categories, serving

as a clearer direction for our future research.

Abstract

This paper describes LIMSI's submissions to the translation shared tasks at WMT'20. This year we have focused our efforts on the biomedical translation task, developing a resource-heavy system for the translation of medical abstracts from English into French, using back-translated texts, terminological resources as well as multiple pre-processing pipelines, including pre-trained representations. Systems were also prepared for the robustness task for translating from English into German; for this large-scale task we developed multi-domain, noise-robust, translation systems aim to handle the two test conditions: zero-shot and few-shot domain adaptation.

1 Introduction

This paper describes LIMSI's submissions to the translation shared tasks at WMT'20. This year we have focused our efforts on the biomedical translation task, developing a resource-heavy system for the translation of medical abstract from English into French, using back-translated texts, terminological resources as well as multiple pre-processing pipelines, including pre-trained representations. Systems where also prepared for the robustness task for translating from English into German; for this large-scale task we developed multi-domain, noise-robust, translation systems aim to handle the two test conditions: zero-shot and few-shot domain adaptation.

Machine translation for the biomedical domain is gaining interest owing to the unequivocal significance of medical scientific texts. The vast majority of these texts are published in English and Biomedical MT aims to also make them available in multiple languages. This is a rather challenging task, due to the scope of this domain, and the corresponding large and open vocabulary, including terms and non-lexical forms (for dates, biomedical entities, measures, etc). The quality of the resulting MT output thus varies depending on the amount of biomedical (in-domain) resources available for each target language.

We participated in this years WMT'20 biomedical translation evaluation for English to French direction. English-French is a reasonably resourced language pair with respect to Biomedical parallel corpora, allowing us to train our Neural Machine Translation (NMT) (Sutskever et al., 2014) with only in-domain corpora and dispense with the processing of large out-of-domain data that exist for this language pair. Our main focus for this year's participation was to develop strong baselines by making the best of auxiliary resources: back translation of monolingual data; partial pre-translation of terms; pre-trained multilingual contextual embeddings and IR retrieved in domain corpora. Two pre-prossessing pipelines, one using the standard Moses tools[1] and subword-nmt (Sennrich et al., 2016b) and other using HuggingFace BERT API were developed and compared. All systems are based on the transformer architecture (Vaswani et al., 2017), or and on the related BERT-fused transformer model of Zhu et al. (2020). If our baselines were actually strong, we only managed to get relatively small gains from our auxiliary resources, for reasons that by and large remain to be analyzed in depth. Our biomedical systems are presented in Section 2.

We also participated in the Robustness translation task, developing a multi-domain, noise-robust and amenable to fast adaptation translation system for the translation direction English-German. Our main focus was to study in more depth the adaptor architecture initially introduced in (Bapna and Firat, 2019) in a large-scale setting, where multiple heterogeneous corpora of unbalanced size are available for training, and explore ways to make the system robust to spelling noise in the test data. The zero-shot system is a generic system which

[1] http://www.statmt.org/moses/

Proceedings of the 5th Conference on Machine Translation (WMT), pages 803–812

does not use any adaptation layer; for our few-shot adaptation submission, we did not use the supplementary data provided by the organizers, which turned out to be only mildly relevant for the test condition, but resorted to a data selection strategy. In any case, our submissions are constrained and only use the parallel WMT data for this language pair; they are further described in Section 3.

2 Bio-medical translation from English into French

2.1 Data sources

We trained our baseline systems on a collection of biomedical corpora, *excluding by principle any out-of-domain* parallel corpus, so as to keep the size of our systems moderate and a reduced training time. Table 1 details the corpora used in training.

Parallel			
Corpus	**Wrds (M)**		**Sents.**

Table 1: Data sources for the English-French biomedical task (before tokenization)

We gathered parallel and monolingual corpora available for English-French in the biomedical domain. These first included the biomedical texts provided by the WMT'20 organizers: Edp, Medline abstracts and titles (Jimeno Yepes et al., 2017), Scielo (Neves et al., 2016) and the Ufal Medical corpus[2] consisting of Cesta, Ecdc, Emea (OpenSubtitles), PatTR Medical and OpenSubtitles. In addition, we used the Cochrane bilingual parallel corpus (Ive et al., 2016)[3] and the Taus Corona Crisis corpus.[4]. We finally experimented with additional in-domain data selected using Information Retrieval (IR) techniques from general domain corpora including News-Commentary, Books and Wikipedia corpus obtained from Open Parallel Corpus (OPUS) (Tiedemann, 2012). These were selected using the data selection scheme described in (Abdul-Rauf and Schwenk, 2009). Medline titles were used as queries to find the related sentences. We used `3-best` sentences returned from the IR pipeline as additional corpus to build the models (these are shown as X7 in table2).

For development purposes, we used Khresmoi, Edp and Scielo test corpora. The Medline test sets of WMT'18 and 19[5] were used as internal test data.

2.1.1 Monolingual sources

Supplementary French data from two monolingual sources were collected from public archives: abstracts of medical papers published by Elsevier from the Lissa portal[6] and a collection of research articles collected from various sources[7] henceforth referred to as Med_Fr (Maniez, 2009). The former corpus contains 41K abstract and totals approximately 7.7M running words; the latter contains 65K sentences, for a little more than 1.5M running words.

These texts were back-translated (Sennrich et al., 2016a; Burlot and Yvon, 2018) into French using a relatively basic neural French-English engine trained with the official WMT data sources for the biomedical task, using the HuggingFace pipeline (see details below). This system had a BLEU score of 31.2 on Medline 18 test set.

Note that back-translation has also been effec-

Symptoms of bacterial pneumonia frequently overlap those present with viral infections or reactive airway disease.
Symptoms of pneumonie bactérienne frequently overlap those present with infections virales or reactive airway maladie.

Figure 1: An example sentence containing pre-translated terms in French

tively used to cater for parallel corpus shortage in the Biomedical domain in (Stojanovski et al., 2019; Peng et al., 2019; Soares and Krallinger, 2019).

2.2 Pre and post-processing

The document level corpora were first retrieved from xml, split[8] into sentences and sentence aligned using Microsoft bilingual aligner (Moore, 2002): these include Cochrane, Scielo and some unaligned documents from Edp. All train, development and test corpora were cleaned by removing instances of empty lines, URLs and lines containing more than 60% non-alphabetic forms.

For tokenization into words and subwords units, two pipelines were considered. The first one is set up as follows (a) tokenize the French and English texts using Moses scripts[9]; (b) compute a joint Byte-pair Encoding (BPE) inventory of 32K units with subword-nmt;[10] (c) generate the translation; (d) detokenize and truecase the output, again with Moses scripts. Systems based on this pipeline are prefixed `M*`. The second one is slightly more complex as it heavily relies on the HuggingFace API[11] for accessing pre-trained BERT models. The corresponding systems are prefixed with `H*` and comprise the following steps: (a) a simple tokenization script, (b) a multilingual segmenter mapping BPE units to pre-trained encodings generated according to (Devlin et al., 2019) as input to the translation system (step (c)). In that case, the MT output is also a sequence of multilingual BPE units that further needs (d) to be reaccentuated and recased, before a final (e) detokenization. Step (d) is non-trivial and is performed by a monolingual translation system trained to convert HuggingFace BPE units into Moses BPE units,[12] which can then be properly reassembled and detokenized as for the Moses pipeline.

2.2.1 Fine-tuning

The fine-tuning process starts from corresponding models trained to convergence, based on BLEU score on dev sets. These are then further fine-tuned using a selected part of the training corpus containing only the Medline abstracts and the three Cochrane corpora, again until convergence. The corresponding systems are post-fixed with `*-ft`.

2.2.2 Pre-translating terms

Medical terms, made of monolexical or polylexical units, are abound in medical terms, and getting their translation right is a very difficult task. Approaches to Biomedical MT have tried to deal this in various ways including explicitly using terminology list (Carrino et al., 2019), domain adaptation (Hira et al., 2019; Stojanovski et al., 2019) and transfer learning (Khan et al., 2018; Peng et al., 2019; Saunders et al., 2019).

We developed systems aimed at improving the translation of terms mainly following the recent proposals of (Dinu et al., 2019; Song et al., 2019). They mostly imply to pre-translate English terms into French, merely replacing the English version with a desired translation in a preprocessing step. The translation system thus inputs mixed-language sentences comprising both English and French words. In our implementation, we followed (Song et al., 2019) and did not mark the pre-translated segments in the input. The target side (French) remained unchanged. Figure 1 displays a sentence extracted from Medline 18 before and after pre-translation (in the latter, French segments are underlined).

Terms are extracted from the French-English version of the Medical Subject Headings thesaurus (MeSH), available in XML format.[13] We extracted a list of about 30K English terms and their preferred translation. This list was extended by searching our training corpus for instances where (a) a term is found in the English sentence; (b) a possible translation is found in the French sentence. Step (b)

Table 2: BLEU scores for the various biomedical systems on Medline 18, 19 and 20 test sets. Superscripts ^{*n} denote the runs submitted: H4, M2, B8.

relies on a much larger list of about 800K possible associations, also extracted from the MeSH. The final term list contains about 40K entries.

Training was performed in two steps: starting with our best system (M3), we resume training with partially pre-translated sentences, using only the following corpora: Cochrane, Medline, Taus and a large portion of Scielo (for a grand total of 2M sentence pairs). This process is performed until convergence. The same fine-tuning process as described above is optionally performed.

In testing, we replace any matching English term with its translation subject to length constraints to avoid irrelevant, ambiguous or accidental matches. We only substitute terms of (source+target) length greater or equal to 7 characters, yielding the pre-translation of 462 and 795 terms respectively in the Medline 18 and Medline 19 test sets. Cases where one term has several translations are disambiguated based on frequency of occurrences in training. These systems appear in the last two rows of Table 2 with the postfix `*-pt`.

2.3 Translation framework

We mostly used two architectures to build our systems: basic Transformer models (Vaswani et al., 2017) as well as BERT-fused transformer models (Zhu et al., 2020). All systems use Facebook's seq-2-seq library fairseq (Ott et al., 2019) with parameters settings borrowed from `transformer_iwslt_de_en`.[14] We used memory efficient FP16 optimizer. The ReLU activation function was used in all 6 encoder and 6 decoder layers, 1024 hidden layer size and batch size of 4K. Training was optimized using Adam and a learning rate of 0.0005 was fixed for all experiments.

For the BERT-based models, we relied on BERT-NMT.[15] This allowed us to build the BERT-fused models using the same architecture and parameters as the baseline transformer models and to establish fair comparisons. In BERT-fused NMT model, the contextual representations are first computed by the BERT model for each token (in the source and target), these are then combined at each encoder and decoder layer using the attention mechanism. Full details are in Zhu et al. (2020).

Given the size of our training data, the "lazy" output dataset implementation was used to enable data loading in the RAM. Systems were trained until convergence based on the BLEU score on the development sets. Evaluation is performed using sacrebleu (Post, 2018). Scores are chosen based on the best score on the development set (Khres+Edp+Scielo) and the corresponding scores for that checkpoint are reported on Medline 18 and

[14] https://fairseq.readthedocs.io/en/latest/models.html

[15] https://github.com/bert-nmt/bert-nmt

Medline 19 test sets. For systems using terminology pre-translation, Khresmoi and Edp were used as development sets.

2.4 Results

Results are in Table 2, where we report BLEU scores for the three tracks explored in this work. $M*$ denotes the Moses tokenization pipeline, $H*$ represents the HuggingFace pipeline and $B*$ denotes the BERT models with HuggingFace tokenization. We computed the scores on Medline 18, Medline 19 and Medline 20 test sets,[16] based on the best checkpoint on our development corpus. Base systems are given on the left, ($\Rightarrow$) identifies the derived (fine-tuned) systems.

We first built baseline systems for the three tracks. `X0` denotes the systems built using only the data provided by the organizers. `X1` are our baseline systems built using all our parallel corpora. We see a unanimous improvement in all tracks ranging from 0.6 to 5.3 BLEU points, which is obtained by adding around $1M$ sentences of additional Cochrane and Taus corpora to the already available $2.9M$ sentences from WMT20. This hints at the relevance of the additional in-domain parallel corpora used.

These baselines `X1` are then further fine-tuned with Cochrane and Medline abstracts as discussed in section 2.2.1, these are shown post-fixed with `*-ft`. All the systems show an improvement in the Moses track. Similarly, we see gain for all tracks for Medline 18 with the highest improvement on BERT-fused systems. For Medline 19 and 20, fine-tuning resulted in a small drop in performance across the board (except than Moses track), for reasons that remain to be analyzed.

Comparing M1-M2 with H1-H2, we see that the Moses pre-processing, which is simpler that HuggingFace's and relies on domain-adapted BPE units is slightly better than the alternative. As using HuggingFace's tools was a way to also experiment with BERT and other extensions, it was nonetheless used for the other systems.

Having established the adequacy of the supplementary parallel corpora, we built systems with back-translated monolingual corpora (section 2.1.1). These appear as X3 and X4 in Table 2. These back-translations were somewhat helpful, not to the extent that we were expecting them to be. Comparing with our baseline X1 systems, we see a small gain of (0.2,0.6,0.8) for our transformer models using HuggingFace tokenization (H1 vs. H3) but no gain for the BERT track (B1 vs. B3). We can speculate about various reasons for this behaviour: (a) genre mismatch with the test set: even though the monolingual corpora also contain scientific texts in biomedical domain, the use of full documents might yield subtle differences in style and term used with what is observed in abstracts, which are more rigidly structured; (b) the use of a comparatively small amount of back-translations as compared to the baseline corpora; (c) the quality of back translations.

Our experiments with pre-translated terms resulted in a small drop of the BLEU scores for the corresponding systems (X5, X6). Our initial analysis of term use[17] in the references and in the system outputs helps understand why this is the case. As it turns out, references translations contain a smaller proportion of *licensed terms* than our baseline translations (55.6% for the reference, 61.1% and 61.6% for respectively X3 and X4), which in turn contain less terms than our term-sensitive systems (H5 and H6, for which these numbers are respectively 68.9 and 64.2). Another way to look at this is to realize that only 58.6% of our pre-translations were actually in the reference. All in all, using more translations from the MeSH makes our output less similar to the reference than the baselines, and contributes to degrade the BLEU score. It is however reinsuring to see that pre-translating terms actually increases the number of terms in the output – in fact, for H5 and H6 we find that respectively 84.2% and 81.9% of these pre-translations are actually copied in the target, even though there was no indication of these French inserts in the mixed-language input. We can also note that the majority of the pre-translated terms were frequent Biomedical terms (such as "patients", "health", etc) that were also correctly translated by the baseline systems. Evaluating these outputs with more useful metrics than BLEU still needs to be performed.

Adding the IR retrieved sentences finally brought us nearly one extra BLEU point on all test sets for the HuggingFace systems, but not much improvement for the BERT-fused system.

[16] Again with our own sentence alignment.

[17] Based on the proportion of source word in our term list that are actually translated with a translation that exists in the Mesh. These proportions are computed on an aggregate of the Medline testsets for 2018, 2019 and 2020, only counting terms with source+target length greater than 7.

2.5 Conclusion

In conclusion, our participation to this year's WMT biomedical task has enabled us to develop basic tools and pipelines for a variety of architectures and to start exploring domain-adapted extensions of a baseline Transformer architecture, using complementary resources, such as supplementary corpora, pre-trained embeddings and terminological resources. If all these extensions were not equally useful, we still were able to develop strong systems for this task that provide us with a solid starting point for further developments of domain-adapted NMT systems.

3 Robustness: translating English challenge test sets into German

3.1 Data sources

Our sole data sources are the parallel corpora distributed by the organizers for the News task, which we significantly down-sampled in order to reduce the overall computational training cost. Monolingual data sources were not considered. These parallel corpora were then grouped into 8 broad domains. Statistics for each corpus / domain are in Table 3.

Our development set is composed of a varied set of common benchmarks, aimed to represent a wide diversity of genres and domains.

3.2 Pre-processing

The first step of pre-processing consists of cleaning the parallel corpora using the following rules: (a) discard sentences based on length (with a maximum length of 99 words), and on the source/target length ratio (in the interval $[2/3; 3/2]$); (b) discard instances of non-English and non-German sentences, using the langid toolkit;[18] (c) remove duplicates sentence pairs. After cleaning, the parallel corpus used in training contains 50,875,449 sentences pairs.

The next step is to lowercase and to tokenize the text into words and subword units. We use the Tokenizer library from OpenNMT.[19] We first lowercased every word, adding a special marker at the beginning of capitalized words, and likewise for uppercased words and segments. For instance, this procedure replaces "It" with "**U** it", and "NOVEMBER RAIN" with "**BU** november **EU BU** rain **EU**". These markers are preserved during the BPE tokenization. We learned a joint BPE vocabulary for both languages using 32K merge operations.

3.3 Training a robust multi-domain system

Our approach to robustness aims at building a system that (a) could fare well for test sets that would be similar to the training domain; (b) could also accommodate data from new, unseen, domains; (c) would be easy to adapt to a new domain (for the few-shot condition); (d) could be robust to spelling noise in the test. Requirements (a)-(c) lead us to implement an extension of the baseline Transformer architecture with residual adapters (more on this in section 3.3.2); to meet requirement (d), we implemented a data augmentation technique described in Section 3.3.3.

3.3.1 Baseline

The baseline system relies on the Transformer Large architecture from (Vaswani et al., 2017). We set the embeddings size and the hidden layers size to 1024. Transformers use multi-head attention with 16 heads in each of the 6+6 layers; the inner feedforward layer contains 4096 cells. Training uses a batch size of 12288 tokens; optimization uses Adam with parameters $\beta_1 = 0.9$, $\beta_2 = 0.98$ and Noam decay ($warmup\_steps = 4000$) and a dropout rate of 0.1 for all layers.

3.3.2 Residual adapters

Our main source of inspiration is the work of Bapna and Firat (2019), who initially introduced the use of residual adapter modules for domain adaption. In a nutshell, this proposal adds an additional, domain-specific layer on top of every layer of the encoder and the decoder. It thus provides us with

[18] https://github.com/saffsd/langid.py
[19] https://github.com/OpenNMT/Tokenizer

a lightweight, computationally efficient alternative to domain adaptation with full fine-tuning, which implies to update all the system parameters. We generalize this approach by training (or rather fine-tuning) a distinct residual adapter for each of the 8 train domains, while freezing the parameters of the baseline (generic) system. These adapter modules are made of 2-layer perceptrons, with an inner ReLU activation function operating on normalized entries of dimension 2048.

Any test sentence from a known domain would then use the corresponding adapter; for test sentences from new domains two options are possible: use only the generic system (without adapter), or use the adapter for the more similar domain. This methodology was chosen in the view of the few-shot task, where a new adapter could easily be learned for a new domain, even with a very small amount of data.

We evaluate the effectiveness of the residual adapters architecture using a varied set of internal test sets. Table 4 reports the BLEU scores of the baseline, generic model, prior to adaptation, as well as the adapted system. As expected, performance are overall better when selecting the appropriate domain for each test set.

We applied this idea to improve the ability our generic model to handle noisy data. Recall that most of the training data (with the exception of the web domain) comes from "clean" sources. To this end, we generated artificial training data for an additional "noise" domain, by automatically altering the source side of randomly selected training data. The noise generation procedure is described below. By doing this way, we expect the model to take advantage of the residual layer when input with noisy data that is similar to our artificial noisy domain, while keeping (a) its good performance on the other known domains, (b) a reasonable behaviour on any other clean data (using the generic baseline model without adapter).

3.3.3 Artificial noise generation

In order to account for possible user generated content (UGC) at test time, we explored the possibility of learning typical UGC noise at the character-level. To this end, we used an automatically scrapped Wikipedia correction corpus (Grundkiewicz and Junczys-Dowmunt, 2014), which has been filtered to keep only word replacements with, at most, a character edit distance of 30% of the word length. In the end, we kept a total of roughly 17.8M pairs of errors and editions. We then trained a character-level Transformer with the same architecture as our base translation model, which had a perfect-match error rate of 22% on the test data partition. Finally, we augmented the original training data by sampling random original words according to a uniform probability distribution and replacing them with the prediction of our character-based UGC noise generator, resulting in the same number of sentences in the original corpora. We have set a 7% probability of replacement, that has been estimated by the percentage of Out-of-Vocabulary words in a real-world UGC corpus. This heuristic later seemed, as discussed in Section 3.4, to overestimate the quantity of noise to be added and, in retrospective, we should have used other metrics to estimate the noise level, such as the n-gram Kullback-Leibler divergence, as discussed in (Alonso et al., 2016; Rosales Núñez et al., 2019). Table 5 displays some examples of noise entries produced by our character-based generator. Regarding these, although typographical errors prevail, due to the nature of automatic filtering of the Wikipedia editions, some learned replacements operations can change the semantics and syntax of the sentence, e.g. (using $\rightarrow$ use), (for $\rightarrow$ in) or (may $\rightarrow$ can); thus introducing unexpected confusion in the training data.

3.4 Results

We report the BLEU scores of our various systems in Table 6. Our submission to the zero-shot evaluation was `FT-Adapt-Noise`, which we found was sub-optimal afterwards. However, interestingly, the residual adapter mechanism proved to substantially outperform the classical fine-tuning of the whole model (i.e. `FT-Full-Noise`). Finally, the residual adapter fine-tuned using the ParaCrawl corpus (`FT-Adapt-Web`) had the best performance on the test set, probably due to the higher similarity of this corpus to the target test. In addition, we noted that the baseline and `FT-Adapt-Noise` output a considerable number of English phrases, leaving most of the source sentence unchanged, whereas the `FT-Adapt-Web` reduced the number of sentences that presented this issue.

In order to assess how much the 172 sentences that were left completely untranslated impact the performance of the `FT-Adapt-Noise` model, we replaced them with the output of the

`baseline` and observed a performance increase to 31.3 BLEU. This suggests that our data augmentation technique introduced confusion to the base model after fine-tuning and the resulting translation system was less adapted to the zero-shot test set.

	robustness-set1	#EN Sents.
Baseline	31.6	120
FT-Adapt-Noise	30.2	172
FT-Full-Noise	24.6	256
FT-Adapt-Web	34.2	34
FT-Full-Web	33.8	49

Table 6: BLEU scores for the EN-De models developed for the Robustness track. We also report, for each system, the number of sentences that were left unchanged.

The design and organization of the few-shot part of the evaluation was not fully satisfactory: while we did train an adapter module using the new data seemingly corresponding to a novel domain, it seems that the corresponding test set was never released and we could not fully evaluate our approach. Working on this task was nonetheless very instructive, and helped us better understand the strength and pitfall of the residual adapter architecture when applied to a very large scale task and in the face of unbalanced, heterogeneous, training data.

4 Conclusions

In this paper, we have described the development undertaken for this year's participation to WMT shared tasks. Taking part to the Biomedical track as allowed us to collect and prepare useful resources (monolingual and bilingual corpora, term lists) for this domain, and to explore several pipelines and translation architectures. The general results are overall satisfactory, even though a deeper analysis of the MT is still needed to strengthen our conclusions. They will also help us prepare for next year tasks, where we expect to work on more language pairs. Our experiment for the Robustness track were less successful: we were not really prepared for the general tone and style that was observed in the zero-shot test set; we also did not understand the general orientation taken for the few-shot adaptation, as it seemed to us that the adaptation data was not really relevant for the only test set that was ever released.

Acknowledgments

This work is (partly) based on computations performed on the Saclay-IA and on the Jean ZAY computing platforms. The authors wish to thank Pierre Zweigenbaum for his help finding French corpora in the biomedical domain and Hicham El-Boukkouri for providing guidance setting up BERT-based systems. The second author wishes to acknowledge the help and guidance of Djamé Seddah and Guillaume Wisniewski; his work is funded by the French Research Agency via the ANR project ParSiTi (ANR-16-CE33- 0021).

Abstract

This article describes the systems submitted by Elhuyar to the 2020 Biomedical Translation Shared Task, specifically the systems presented in the subtasks of terminology translation for English-Basque and abstract translation for English-Basque and English-Spanish. In all cases a Transformer architecture was chosen and we studied different strategies to combine open domain data with biomedical domain data for building the training corpora. For the English-Basque pair, given the scarcity of parallel corpora in the biomedical domain, we set out to create domain training data in a synthetic way. The systems presented in the terminology and abstract translation subtasks for the English-Basque language pair ranked first in their respective tasks among four participants, achieving 0.78 accuracy for terminology translation and a BLEU of 0.1279 for the translation of abstracts. In the abstract translation task for the English-Spanish pair our team ranked second (BLEU=0.4498) in the case of OK sentences.

1 Introduction

General purpose translation systems usually perform poorly where domain specific knowledge is required (Koehn and Knowles, 2017). Therefore, it is essential to develop translation systems for specific domains. However, high quality parallel corpora for domain specific tasks are only available for a few major languages and obtaining in domain translated data for the majority of language pairs becomes a challenge. With such scarcity of resources, various domain adaptation techniques have shown promising results (Currey et al. 2017, Saunders et al. 2019, Sennrich et al. 2017).

The biomedical domain is of great interest for the application of machine translation. It is a sector of great importance in society, even more so after the advent of COVID-19, where the handling of documentary information plays a major role. Therefore, it is a scenario where machine translation can be of great help in order to facilitate the flow of information between different languages.

We can find different works in the literature that address the task of developing NMT systems adapted to the biomedical domain (Yepes et al., 2017; Sennrich et al., 2017; Khan et al., 2018). In contrast, few papers focus on language pairs where training data is scarce. This is precisely the case of the task of translation from English to Basque. The work of Soto et al. (2019) is specially relevant in this case, which presents a clinical domain oriented system for Basque-Spanish based on RNN and Transformer architectures and which does not require bilingual domain texts but only bilingual clinical terminology (SNOMED CT).

Our participation in the Biomedical Translation Shared Task addresses the translation of biomedical terminology from English to Basque and the translation of biomedical abstracts from English to Basque and from English to Spanish. Given the scarcity of real parallel biomedical domain corpora, our approach focused on different strategies to combine open domain data with in-domain biomedical data. In the case of the English to Basque translations, back translation technique has been applied to generate synthetic examples from a real biomedical Spanish-Basque corpus and several monoligual in-domain Basque corpora have been merged to the training data by copying target side examples to source. Furthermore, we have considered finetuning previously available open domain systems in order to take advantage of the learnt general, open domain patterns.

This article is structured as follows: the following section reviews the most relevant related works. Section 3 describes the systems presented to the sub-tasks that include the English-Basque and English-Spanish pairs, as well as the results

Proceedings of the 5th Conference on Machine Translation (WMT), pages 813–819
Online, November 19–20, 2020.

obtained in the experimentation. Section 4 presents the results obtained in the official evaluation, and finally, we end the paper outlining the most relevant conclusions drawn from this work.

2 Related work

Most of the related work on domain adaptation focuses on using either in-domain monolingual corpora, synthetically generated corpora or small parallel corpora.

Regarding in-domain monoligual corpora, Currey et al. (2017) analyze the benefits of augmenting available data by copying the target side monolingual data to source and training the system. Results show significant gains in accuracy on named entities and words remaining identical in source and target languages.

Several studies show the effectiveness of generating synthetic parallel corpora for domain adaptation. Sennrich et al. (2015) use the back translation technique with target monolingual data to strengthen the decoder, Zhang and Zong (2016) make use of source side monolingual data and Park et al. (2017) use both, source and target monolingual data to improve in-domain translations.

Finally, when in-domain parallel corpora is available, previous work focuses on mixed domain NMT systems by using both in-domain and out of domain data. Chu et al. (2017) propose to use control tags to mark in-domain sentences prior to concatenating multiple domain corpora. Sajjad et al. (2017) compare different methods for training a multi domain system, such as, concatenation, interactively training on different domains, selecting out of domain data close to the in domain data and ensembling different domain models. Wang et al. (2017) exploit the internal sentence embeddings to find sentences that are close to in-domain data from out of domain data.

Several works in the literature address the task of developing NMT systems adapted to the biomedical domain. Saunders et al. (2019) apply transfer learning technique by training on a large, general domain corpus and finetuning a series of systems on different biomedical domains. They perform multi domain ensembling to further improve the results. Khan et al. (2018) iteratively apply transfer learning on various biomedical domains.

Regarding works dealing with Basque the work of Soto et al. (2019) presents a clinical domain oriented system for Basque-Spanish based on RNN and Transformer architectures, which does not require bilingual domain texts but bilingual clinical terminology (SNOMED CT). They also analyse different back translation techniques. Aimed at translating clinical terminology into Basque, we find the work of Perez-de Viñaspre (2017) which proposes a system for translating SNOMED CT into Basque by combining lexical resources, transliteration of neoclassical terms, generation of nested terms and a domain-adapted RBMT system.

3 Experiments

In this section we describe the experiments carried out when training the translation systems. We compare the results obtained by the systems on different open domain and in-domain test sets prior to selecting the best runs to submit for the biomedical translation task. We also detail the Transformer architecture used and its parameters.

3.1 Datasets

For the experiments, we considered open domain general data and in-domain task specific data for fine-tuning purposes. Open domain data comprises the publicly available Paracrawl v5 (Esplà et al., 2019) corpus for English-Spanish and a Elhuyar's internal synthetic corpus for Basque-Spanish.

Due to the scarcity of in-domain data in the case of English-Basque, back translation has also been applied to generate synthetic examples. Furthermore, we augmented training data by using monolingual Basque data gathered from artificially generated hospital notes, SNOMED-CT terminological content and Wikipedia biomedical articles. We have created parallel data by copying the Basque sentences to source so that each source sentence is identical to the target sentence. Table 1 offers a summary of the corpora used.

3.2 Architecture

For training the models the Transformer architecture (Vaswani et al., 2017) has been chosen. Specifically, the Python implementation of the OpenNMT (Klein et al., 2017) library has been used. Transformers are based on an encoder-decoder system with an attention mechanism. Both the encoder and the decoder are composed of 6 layers composed in turn by a feed forward network and a multi-head attention mechanism. Default values of the architecture without any optimization of the parameters have been applied. The size of the recurrent neu-

Corpus	Pair	Domain	Description	Sentences
Elhuyar synthetic (ELH Syn)	EN-EU	Open	Elhuyar's internal synthetic corpus obtained by translating an internal ES-EU corpus with our best performing ES-EN out of domain system	6.9M
EHU books	EN-EU	Biomed.	Collection of biomedical books translated from English to Basque	22.6k
ICD-10	EN-EU	Biomed.	ICD-10 codes translated from English to Basque and publicly available for the shared task	25.9k
EHU Synthetic (EHU Syn)	EN-EU	Biomed.	Synthetically generated corpus by back translating an in domain EHU book collection dataset (ES-EU) from Basque to English with a previously trained in domain EU-EN system	303k
Hospital notes	EU	Biomed.	Artificially generated hospital notes to use as guide for practitioners	2.2k
SNOMED	EU	Biomed.	Automatic translation of the terminological content of SNOMED-CT (2020), no manually revised	105k
Wikipedia	EU	Biomed.	Medical domain articles from Wikipedia	1.3k
Paracrawl v5 (PCv5)	EN-ES	Open	Publicly available Paracrawl v5 corpus, which comprises parallel segments crawled from the web	33.3M
Biomedical (Mix)	EN-ES	Biomed.	Comprises subsets of the Scielo dataset (Soares et al., 2018), and previous years' WMT shared task datasets	560k

Table 1: Size of corpora used for training the systems.

ral network of each layer is 512. Thus, 512 size embeddings have been used for both source and target sentences. Adam optimizer has been used during the training, and a learning-rate of 2 with a warm-up phase of 8000 steps. The dropout ratio is 0.1 and the batch size is 4096 sentences. All models have been trained until the results on the development set stopped improving.

To avoid the open vocabulary issue and for a better translation of unknown words, BPE tokenization (Sennrich et al., 2016) has been applied to source and target sequences. Rare or unseen words are represented as a sequence of subword units. In the case of Basque, this encoding is particularly useful as declensions generate a larger vocabulary.

3.3 EN-EU experiments

In this section we provide a detailed description of the experiments carried out for the English-Basque pair. We describe the systems built and the results obtained on different test sets. Looking for a robust experimental setup, we conducted both open domain and in-domain evaluation. A brief description of the test sets can be found on Table 2.

3.3.1 Systems

For the English-Basque pair we trained the following systems:

Baseline1. A strong baseline by pivoting Elhuyar's best out of domain EN-ES and ES-EU models. These models are trained on the PCv5 corpus and a Elhuyar's internal Spanish-Basque corpus respectively.

Baseline2. A further improvement of Baseline1, by fine-tuning the EN-ES pivoting system with Medline and SCIELO in-domain biomedical data.

Baseline3. A previously available out of domain EN-EU system trained with back translated synthetic data.

Baseline4. A simple baseline trained with the task's official in-domain data (ICD-10 corpus).

SystemA1, SystemA2 and SystemA3. These systems are the result of fine-tuning Baseline3 with in-domain data. SystemA1 uses a subset (250k) of ELH Syn open domain corpus as well as shared task ICD-10 in domain data. A small portion of the ICD-10 corpus (1k) is used for validation. SystemA2 is a variant of SystemA1 by adding more in domain data from the EHU books corpus. A small subset of the EHU books corpus (1k) is also added to the validation set. Finally, SystemA3 includes a subset (5k) of the out of domain ELH Syn corpus in the validation set in order to prevent the system from forgetting about prior out of domain knowledge.

SystemA4. A variant of SystemA3 using all the available ELH Syn open domain data.

SystemB1. This system was trained by adding synthetically generated EHU Syn in-domain data to the data used in SystemA4. To create synthetic data, a fine-tuned EU-EN model has been used to back translate an internal ES-EU biomedical corpus gathered from a collection of EHU books.

SystemB2. This system was trained by further augmenting data from SystemB1 with copied monolingual Basque target data from the shared task (Hospital notes, SNOMED terminology and Wikipedia).

SystemC. A variant of SystemB2. Synthetic Medline data from the WMT19 EN-ES biomedical shared task was added to the validation set to improve the performance on the Medline domain.

Test	Pair	Domain	Description	Sentences
Synthetic (Syn)	EN-EU	Open	Subset of the Elhuyar's internal synthetic corpus	5k
EHU books (EHU)	EN-EU	Biomed.	Subset of the collection of biomedical books translated from English to Basque	1k
Medline pro (PRO)	EN-EU	Biomed.	Professional translation from Spanish to Basque of the WMT19 ES-EN shared task data	200
Terminology (ICD-10)	EN-EU	Biomed.	Subset of the shared task in-domain ICD-10 terminology set	368
Paracrawl v5 (PCv5)	EN-ES	Open	Subset of the Paracrawl v5 corpus	5k
Elhuyar TMs (ELH)	EU-ES	Open	Data collected from Elhuyar's internal translation memories	1k
WMT18	EU-ES	Biomed.	WMT18 biomedical task test set	277
WMT19	EU-ES	Biomed.	WMT19 biomedical task test set	368

Table 3: BLEU scores for the English to Basque experiments on out of domain and in-domain test sets.

3.3.2 Results

Table 3 shows BLEU scores for the English to Basque experiments on out of domain and in-domain test sets (Table 2).

As for abstract translation, SystemA4, SystemB1, SystemB2 and SystemC showed a significant improvement on those test sets when compared to the other trained systems. In particular, SystemB2 obtained the best results on PRO test and SystemC the second best result.

The gap between SystemA4 and the other three SystemA's showed that using all the available out of domain data helps avoiding the "catastrophic forgetting" phenomena, where all previous knowledge fades when learning new in-domain examples.

SystemB1 introduces in-domain synthetic data in the training process, which significantly improves the results on the EHU test. This is due to the fact that synthetic data and the EHU test set share the same domain (EHU biomedical books). However, the drop on the PRO test is almost insignificant and it also improves all the baselines on the Synthetic test.

SystemB2 further improves the results on the PRO test set by adding monolingual corpora to the training data and SystemC shows the effect of the validation set by adding more biomedical domain data to the validation set. Both systems improve all the baselines on every test set.

SystemB2 (run1), SystemC (run2) and Baseline2 (run3) were submitted as the best runs for the English to Basque abstract translation task.

Terminology translation task greatly differs from the abstract domain which can be clearly seen in the results. In this case, the best results are obtained by SystemA1 which only includes a small part of the available out of domain data. Furthermore, results are not distant from Baseline4 which was trained with ICD-10 training data. This behaviour shows the specificity of the task where previous complete sentence translation knowledge is not essential.

SystemA2 (run1), SystemA1 (run2) and Baseline4 (run3) were submitted as the best runs for the English to Basque terminology translation task.

3.4 EN-ES experiments

Below we present the different systems trained for the English-Spanish pair and the results obtained

for each of them.

3.4.1 Systems

For the English-Spanish pair we trained the following systems:

Baseline1. We have considered a strong baseline by using Elhuyar's best out of domain EN-ES model. This model was trained on the PCv5 corpus.

SystemA. This model has been trained from scratch mixing in-domain and out domain data. In-domain data comprises previous years' shared tasks Medline data and a subset of the SCIELO dataset. Out of domain data was obtained from the PCv5 corpus.

SystemA'. A variant of SystemA by averaging the three best performing checkpoints.

3.4.2 Results

Table 4 shows BLEU scores for the English to Spanish experiments on out of domain and in-domain test sets (Table 2).

SystemA improves the baseline on all the test sets and SystemA' further improves those results obtaining the best results for the task. Similar to the English to Basque abstract translation task, for the English to Spanish pair adding in-domain data and fine-tuning a previously trained out of domain system improved the results. Furthermore, averaging the first three best checkpoints helped improving the results of the best checkpoint.

SystemA' (run1), SystemA (run2) and Baseline1 (run3) were submitted as the best runs for the English to Spanish abstract translation task.

4 Official results

For the English to Basque abstract translation task we selected the PRO test as the most representative one when choosing the best runs for submission. We assumed that this test set would be the closest to the official task test. The EHU test set was also a great indicator of how robust our system was for the biomedical domain.

BLEU scores were calculated using the multi-eval tool and tokenization as provided in Moses. Table 5 shows the performance of all the submitted runs for the official abstract translation test set. Our submitted run2 has obtained the best score on the official task test, achieving a 0.1279 BLEU score. When compared to other teams, all our submitted runs significantly outperform all the runs. It is worth mentioning that our Baseline2 (run3) which is based on pivoting between two systems (EN-ES and ES-EU) has obtained really close results which indicates that some biomedical knowledge was present in the Spanish to Basque system.

In the case of the terminology task, ICD-10 test set is the official validation task and therefore the most representative one for choosing the best runs.

For the evaluation of terminology we provide two metrics: (i) accuracy, by relying on strict matches (case insensitive) between ground truth ans predictions; and (ii) BLEU score, as measured by the NLTK module sentence_bleu. Table 6 shows the performance of all the submitted runs for the official terminology test set.

Our best submitted run has obtained the best score on the official task test, achieving 0.78 accuracy and a 0.7373 BLEU score. When compared to other teams, all our submitted runs outperform all the runs, except for DCU_MT's run2. It is worth mentioning that out Baseline4 (run3) which was trained on task's English-Basque data has outperformed almost all of the others teams' results. This highlights the improvements obtained by our systems over the baseline.

Finally, for the English to Spanish abstract translation task WMT19 and WMT18 test sets were selected as reference for selecting the best runs.

Table 7 shows the performance of all the submitted runs for the official English to Spanish abstract translation test set. Our best submitted run has obtained the fifth best score on all sentences achieving a 0.4364 BLEU score and the second best team with OK sentences (BLEU=0.4498). In this case, our submitted baseline (run3) also shows a great robustness, indicating some prior biomedical domain knowledge.

5 Conclusions

For the Biomedical Translation Task 2020, we considered several strategies combining open domain and in-domain biomedical data. We have successfully applied transfer learning by fine-tuning a previously available open domain system with in-domain specific data. To tackle the scarcity of English-Basque domain data, we have performed data augmentation by back translating real data.

The systems submitted for the terminology and abstract translation tasks for the English-Basque pair have ranked first on the official task test, achieving 0.78 accuracy for terminology translation and a BLEU of 0.1279 for the translation of

of the pivoting pairs (EN-ES) we have created a robust baseline for the biomedical domain.

Adding monolingual corpora to the training data, as copied target, seems to improve the decoder by adapting the systems to better perform on domain specific terminology. Even though some noise is introduced by copying the target to the source side, the results are improved.

Terminology task showed promising results when translating biomedical domain terms, which could lead to a production ready system.

YerevaNN's Systems for WMT20 Biomedical Translation Task: The Effect of Fixing Misaligned Sentence Pairs

Karen Hambardzumyan[1], Hovhannes Tamoyan[1,2], and Hrant Khachatrian[1,3]

[1]YerevaNN

[3]Department of Informatics and Applied Mathematics, Yerevan State University

Abstract

This report describes YerevaNN's neural machine translation systems and data processing pipelines developed for WMT20 biomedical translation task. We provide systems for English-Russian and English-German language pairs. For the English-Russian pair, our submissions achieve the best BLEU scores, with en→ru direction outperforming the other systems by a significant margin. We explain most of the improvements by our heavy data preprocessing pipeline which attempts to fix poorly aligned sentences in the parallel data.

1 Introduction

Biomedical machine translation is a perfect playground to develop narrow domain neural machine translation models. In such tasks, the available parallel in-domain data is usually limited and noisy which creates many challenges.

In the previous works (Bawden et al., 2019), researchers focused on transfer learning methods (Saunders et al., 2019) or attempted to mix the training data with other sources (Peng et al., 2019) to address the issue of data scarcity. In this work, we show that the transfer performance is very dependent on the quality of the training data, and with a little effort, it is possible to improve the given MEDLINE training data and gain a significant performance boost.

We have manually created a much higher quality subset of the original MEDLINE training data for local evaluation purposes. The insights collected during this manual analysis was then used to fix the most common issues within the training data. In particular, we noticed that the original dataset contained paper abstracts in two languages without sentence-level alignments, and the training corpus provided by the organizers was created using an automated sentence segmentation and alignment process, which was not perfect. We built a data pipeline[1] that handles 1) cleanup, 2) sentence segmentation, 3) alignment of translation sentence pairs and 4) preprocessing.

In our experiments, we did not use any data source other than MEDLINE. We chose our baseline model and two other models with the highest BLEU scores on a local test set as our three submissions. The best ones got 35.2% BLEU on English-German and 41.3% on German-English test sets. For English-Russian and Russian-English directions we reached BLEU scores of 37.9% and 43.2% respectively, which are the best scores among all submissions of WMT20 Biomedical Translation Task. Moreover, our models are cheap to train: the average training time of our best models is approximately 30 minutes on a single NVIDIA Titan V GPU.

The paper is organized as follows: Section 2 presents fine-tuning details and evaluation methods for our NMT systems, Section 3 describes the data used in the experiments and the data processing pipeline, Section 4 presents our novel method of monotonic alignment based on multilingual language models. Section 5 discusses the results.

2 System Description

2.1 Pretrained Models

All our NMT models are built on top of WMT19 News Translation task winner models by Ng et al.. We employ FairSeq library (Ott et al., 2019) to fine-tune pretrained models on the in-domain translation data.

The pretrained models are based on `transformer_wmt_en_de_big` architecture (Vaswani et al., 2017) with a modified feedforward

[1]Our data pipeline is available at https://github.com/YerevaNN/parasite

Proceedings of the 5th Conference on Machine Translation (WMT), pages 820–825
Online, November 19–20, 2020.

dimension (8192) and a shared matrix for input and output embeddings. Additionally, en↔de models share vocabulary and embeddings for both source and target sides.

2.2 Fine-Tuning

We start fine-tuning `single_model` versions of Facebook's WMT19 models[2] on in-domain parallel data and stop the training when the perplexity on the validation set does not improve for 5 consecutive epochs.

To fight noisy training data we use label-smoothed cross-entropy loss (Müller et al., 2019).

The neural architecture and related implementation details cannot be changed in the fine-tuning scenario. While this limited our experimental setup, however, it also allowed us to care less about hyperparameter tuning and focus on other parts of the pipeline.

2.3 Implementation Details

The hyperparameters for our baseline models (`run1`) are as follows. The models are fine-tuned on the training data using an inverse-square-root learning rate schedule with 4000 warm-up steps with an initial learning rate of 10^{-5}. Instead of using a fixed batch size, we make batches of maximum 3584 tokens to fit in the memory. For label smoothing, we set a smoothing coefficient of 0.1. Unlike the pretrained models, we use standard Adam betas and disable dropout.

Training with bigger batches (implemented using gradient accumulation, a single update per 128 batches) not only helped us to reduce total training time 4x but also resulted in better models (including our best submissions `run2` and `run3`).

All the models are trained on a single NVIDIA Titan V GPU with 16-bit floating-point operations. The average duration of fine-tuning with bigger batches was 30 minutes.

Finally, we use a beam size of 32 in the inference mode.

2.4 Evaluation and Model Selection

We use two kinds of validation sets for model selection. For early stopping, we calculate the perplexity on a regular validation set which is extracted from the training data. To determine our best models for submissions, we use a separate in-domain dataset which we call "local test set" and calculate BLEU score on it. All BLEU scores are calculated with SacreBLEU case-insensitive configuration.

3 Data

3.1 Parallel Data

For all directions, we use only MEDLINE training data provided by the shared task organizers. We take random 50 documents from the training data as the validation set. In case of en↔de we use OK-tagged sentence-pairs from WMT'19 biomedical translation test set (Bawden et al., 2019) as the *local test set*. To have a *local test set* of a similar quality for en↔ru, we take another random 50 documents, then manually fix misaligned sentences and filter out a few pairs with incorrect translations.

During the manual review of the en↔ru *local test set* we noticed that the provided data was poorly aligned, and it was possible to get high-quality sentence pairs by re-aligning the sentences (only 9 sentences were dropped except the titles/subtitles, out of 504 sentences). Then we tried to use these insights to build a new automated system for monotonic alignment of the sentences (described in Section 4).

Table 1 exhibits the most common issues found in the MEDLINE training data:

- The bitext documents may be misaligned: the translation of a source sentence may appear on a different line, or even on multiple lines, in the target side,
- Headings and section names may occur next to a sentence on one side only, or on both sides,
- English documents may start with titles (often wrapped in brackets), while the Russian ones do not.

These issues are too common in the training set, and simply removing incorrect pairs of sentences would significantly reduce the dataset. Instead, we decided to fix the misaligned sentences to preserve as much parallel content as possible. The solution is described in Section 4.

3.2 Monolingual Data

Although the base models we use are already trained with backtranslation, we try to fine-tune with backtranslation as well. We obtain translations

Table 1: A hand picked example from MEDLINE en↔ru training set (document #26978637) which demonstrates the most common issues in the dataset. The first line in English includes the title of the paper which is not present in Russian. The English version of the main content of the first line in Russian is given on the second line. Line 3 in English has an extra heading which corresponds to Line 2 on the right side. The rest of the third line on the left matches to the third line on the right side, and the last two lines are correct.

with the fine-tuned models mentioned above, then fine-tune *new* models on a mixed data consisting of the regular parallel training data and backtranslated data with equal proportions.

To perform backtranslation we need a set of in-domain monolingual sentences that do not overlap with the test set. To train backtranslated de↔en and ru ↔ en directions, we took all English sentences from all parallel corpora available from MEDLINE (both training and test sets) excluding the parallel corpora we would eventually train on. This way we collected 296,052 (236,379) English sentences for German (for Russian). To obtain a parallel corpus we translated them using our models, and then filtered them using the same process as with the regular training data (see the next subsection). We ended up with 281,054 (220,916) sentence pairs for en↔de (en↔ru).

We did not perform backtranslation from Russian or German (directions en→de and en→ru), as we did not expect to find in-domain sentences that are not present in MEDLINE.

When translating the monolingual sentences, we tried `sampling`, `sampling-top5`, `greedy`, `beam`, `beam+noise` decoding methods similar to (Edunov et al., 2018), but no major difference in terms of the final BLEU score has been observed.

3.3 Preprocessing

The preprocessing pipeline for our models has to be identical to the one used for pretrained models. First, we perform punctuation normalization (quotation, commas, numbers, replacing punctuation and removing control characters) using `SacreMoses` library. Then, we tokenize the resulting sentences using Moses (Koehn et al., 2007) tokenizer with aggressive dash splits and escaping XML entities. Finally, we use subword segmentation (Sennrich et al., 2016) (`fastbpe` implementation) with BPE codes from pretrained models, with 24k and 32k splits for Russian and for joint English & German, respectively.

We perform additional filtering of the parallel data before the training: we skip those sentence pairs where 1) source or target sentence has more than 250 subwords and/or 2) the ratio of lengths of the source and target sentences is more than 3/2.

During inference, we truncate sentences to the first 1024 subwords (the number of the positional embeddings).

During our early experiments we noticed several issues with our preprocessing pipeline which we fixed for the later experiments. In particular, we noticed that some `sacremoses` command line flags were broken, and the out-of-the-box inference tool from `FairSeq` did not fully replicate the preprocessing pipeline used for training (punctuation normalization and vocabulary-aware subword segmentation). The original pipeline (called *v1*) was used for our baseline models. The later experiments used the fixed implementations of `sacremoses` and `FairSeq` (denoted by *v2*).

4 Monotonic Alignments

The problems of the training set described in Section 3.1 can be caused by poor 1) XML parsing, 2) sentence segmentation, or 3) monotonic segment alignment method. Here we describe a novel method for monotonic sentence alignment using multilingual language models and discuss the contribution of its hyperparameter choices. Multilingual language models have been previously shown to be effective in parallel data mining (Kvapilíková et al., 2020). We also compare our approach to the baseline data pipeline by the shared task organizers which is based on `Syntok` segmentation system and `GMA` (Melamed, 2001).

Our method of monotonic sentence alignments is as follows: we calculate a similarity matrix of all source-target candidate pairs and decode pairs to maximize the similarity of the resulting sentence pairs. We consider two approaches for the decoding step: greedy and dynamic.

4.1 Similarity Matrix

The similarity matrix is calculated using Euclidean distances of sentence embeddings from a pretrained multilingual language model. We found `xlm-roberta-large` (Conneau et al., 2019) to be the best one. In order to obtain a fixed size vector for each sentence, we simply take the average of the wordpiece embeddings (Cer et al., 2018; Artetxe and Schwenk, 2019).

We also attempt to address some common issues concerning the given MEDLINE abstracts that may harm the quality of the alignments: 1) we remove titles from the English version that are absent in the Russian version, 2) we detect the headings that often get attached to adjacent sentences, 3) we lowercase the text before obtaining embeddings (as the English headings are written in capitals, unlike the Russian ones), 4) we experiment with different sentence segmentation systems such as SciSpacy (Neumann et al., 2019) (in-domain, for English) and Razdel[3] (focused on Russian), 5) we also penalize candidates with source/target length ratios exceeding 2. Additionally, we consider using normalized distances and the margin based approach described in (Artetxe and Schwenk, 2019).

[3] `https://github.com/natasha/razdel`

4.2 Greedy Approach

In greedy approach, we construct the set of correct sentence pairs in an iterative process. Given the similarity matrix, at each step we add the sentence pair with the maximum similarity score. As there is an assumption that the alignments should be monotonic, after each step we exclude all remaining candidate sentence pairs that would break the monotonicity. Our implementation finds at most one target sentence for a source sentence (and vice versa).

Algorithm 1: Greedy decoding

$S_N, T_M \leftarrow$ source and target sentences
$D_{i,j} \leftarrow Sim(S_i, T_j)$
$Res \leftarrow \{\}$
while $|Align| < \min(N, M)$ **do**
  $i, j \leftarrow \arg\max(D)$
  $Align \leftarrow Align \cup \{i, j\}$
  $D_{i..N,0..j}, D_{0..i,j..M} \leftarrow 0$
end
Result: Align

4.3 Dynamic Algorithm

In the dynamic algorithm, we consider maximizing the sum of the similarity scores of the selected sentence pairs according to the given matrix. Our implementation of this approach, unlike the greedy one, can produce sentences consisting of multiple (up to K) segments on each side. To find the mapping with the best total similarity score we use dynamic programming.

5 Results

For WMT20 Biomedical Translation Task we prepared three submissions: `run1` for all directions was the baseline model, while for `run2` and `run3` we chose the best models according to their BLEU score on the local test set at the time of the submission. In `run2` and `run3`, all the models besides de→en of `run2` are trained with our data pipeline and bigger batches. The official BLEU scores on samples with "OK" aligned sentences alongside with our local test set are presented in Table 2.

For de→en of `run2`, backtranslation data was collected with beam search (size of 8), in case of ru→en, we had noise added similar to Edunov et al., and for `run3` we used a simple sampling strategy. Our experiments with backtranslation showed no

BLEU Scores on WMT20 Test / Local Test				
Models	**en→de**	**de→en**	**en→ru**	**ru→en**
run1	35.2 / 34.5	41.3 / 45.4	32.6 / 27.7	NA / 30.7
run2		41.4 / 44.7	39.4 / 31.6	43.3 / 33.0
run3	35.2 / 35.1	41.3 / 45.6	37.9 / 31.8	43.2 / 33.1

Table 2: BLEU scores of our submissions

Algorithm 2: One-to-many (K) dynamic decoding

$S_N, T_M \leftarrow$ source and target sentences
$Best_{N,M} \leftarrow 0$
$Res_{N,M} \leftarrow \{\}$
for $i = 1 \rightarrow N$ **do**
  for $j = 1 \rightarrow M$ **do**
    for $u, v = 1 \rightarrow K$ **do**
      $candidate \leftarrow Best_{i-u,j-v} + Sim(S_{i-u..i}, T_{j-v..j})$
      if $candidate > Best_{i,j}$ **then**
        $Best_{i,j} \leftarrow candidate$
        $Res_{i,j} \leftarrow Res_{i-k,j} \cup \{S_{i-k..i}, T_{j-v..j}\}$
      end
    end
  end
end

significant advantage of any of those compared to the others.

For `run2` and `run3`, we used v2 preprocessing, the sentence splitting was done with `scispacy` (for English and German) and a slightly modified version of `razdel` (for Russian).

After our submissions, we further improved our data pipeline. Table 3 is an empirical analysis of the effect of different components of our data pipeline, as measured by the performance on the final translation task. Each row of the table corresponds to a model trained on the data obtained from a pipeline with certain components enabled. There is no other between the rows, all models are trained by fine-tuning the general domain baseline using our default hyperparameters. We measure the BLEU score on the local test set.

Fixing the issues of the standard preprocessing (v2 vs. v1) gives a significant boost, especially when decoding to Russian (en→ru direction). The effect of training with bigger batch sizes gives only a slight improvement, while the absolute training duration reduces drastically.

Model	**en→ru**	**ru→en**
baseline model	27.7	30.7
+ v2 preprocessing	30.5	31.3
+ train with bigger batches	30.7	31.3
+ greedy alignments	30.1	31.8
+ detect section names	30.7	32.3
+ remove titles	31.3	**32.5**
+ optimize total similarity	30.4	32.2
+ normalize distance matrix	30.8	32.1
+ penalize source/target ratio	31.2	31.5
+ one-to-many (K=3)	**32.2**	32.3

Table 3: The effect of different components of the data processing pipeline. We report BLEU scores on the local test set.

As mentioned previously, there were issues with section names and titles in the provided parsed documents. After addressing these issues, our greedy approach gives better alignments.

The total similarity optimization using dynamic programming is not always better than the greedy method, but the performance improves for en→ru with another +1.1% BLEU score. Overall, the new data pipeline gives an enhancement in NMT performance: +1.6% BLEU for ru→en and a bigger gain of +4.5% BLEU score for en→ru.

Although we observe consistent performance improvement for both directions en↔ru, the effect for en→ru direction is more significant. We could not determine the reason for such assymmetry.

6 Conclusion

This work presents the systems our team developed for English-German and English-Russian language pair tracks of WMT20 Biomedical Translation Task. We achieve the best results on the official test set for English↔Russian language pair, outperforming competitors by a significant margin on English→Russian direction. We show that it is possible to improve the performance of neural machine translation models by simply improving the quality of the in-domain parallel

data. The suggested method for monotonic sentence segment alignment based on pretrained multilingual language models demonstrated promising results. We explored how different components of our data processing pipeline contributed to the quality of the resulting translation systems. In future work, we plan to investigate the applicability of this pipeline to a wider set of language pairs and domains.

Acknowledgments

We would like to thank Adam Bittlingmayer from ModelFront for useful discussions on the quality of parallel corpora. All experiments were performed on Titan V GPUs donated to YerevaNN by NVIDIA.

Abstract

This paper describes the machine translation systems proposed by the University of Technology Sydney Natural Language Processing (UTS_NLP) team for the WMT20 English-Basque biomedical translation tasks. Due to the limited parallel corpora available, we have opted to train a BERT-fused NMT model that leverages the use of pretrained language models. Furthermore, we have augmented the training corpus by backtranslating monolingual data. Our experiments show that NMT models in low-resource scenarios can benefit from combining these two training techniques, with improvements of up to 6.16 BLEU percentage points in the case of biomedical abstract translations.

1 Introduction

Nowadays, most of the literature and scientific terminology produced in the biomedical field is in English, which limits the access to this information by non-English speaking researchers, doctors and patients. Thus, it would be very useful to avail of machine translation systems that can effectively translate this information into other languages, so that more people can be able to access it and benefit from it.

However, many of the world languages lack sufficient parallel corpora to properly train machine translation systems in this domain. State-of-the-art neural machine translation (NMT) models (Sutskever et al., 2014; Bahdanau et al., 2015) suffer from overfitting when trained on insufficient data, and thus fail to generate accurate translations (Koehn and Knowles, 2017).

In this paper we address this problem for a low-resource language, Basque. We have taken part in the WMT20 Biomedical Translation challenge, which has released two interesting shared tasks involving this language, namely, the English-to-Basque translation of biomedical article abstracts and the English-to-Basque translation of medical terminology. In order to overcome the issue of having limited supervised training data, we have decided to apply two promising ideas proposed in the literature. First, we have applied transfer learning by training a *BERT-fused* NMT model (Zhu et al., 2020) that uses source-language contextual embeddings inferred by a pretrained language model (LM) as additional input features, both in the encoder and in the decoder. Second, we have augmented the training corpus using backtranslation (Sennrich et al., 2016; Burlot and Yvon, 2018). For this, a BERT-fused NMT model has been trained in the opposite translation direction (Basque → English) to translate sentences from large monolingual corpora (e.g. Wikipedia, medical texts).

The experiments have shown that an NMT baseline can greatly benefit from combining these training techniques. The three best performing systems in both tasks (terminology and abstracts) have been submitted to the WMT20 biomedical translation shared task under the UTS_NLP team name.

2 Related Work

2.1 Pretrained LMs

Pretrained LMs have been one of the most remarkable advancements in transfer learning for NLP in recent years. They are large neural networks that are trained over massive datasets (millions of sentences) in an unsupervised manner, and can effectively learn the regularities/patterns of a language. Then, such general networks can be applied to efficiently train smaller networks for downstream tasks, using much smaller annotated datasets. ELMo (Peters et al., 2018), BERT (Devlin et al., 2019) and GPT-2 (Radford et al., 2018) are some examples of pretrained LMs that have

Proceedings of the 5th Conference on Machine Translation (WMT), pages 826–832
Online, November 19–20, 2020.

achieved state-of-the-art results in various natural language understanding tasks such as, among others, sentiment analysis, paraphrase detection, and question answering.

In NMT, various recent works have proposed incorporating pretrained LMs into the standard encoder-decoder architecture. Lample and Conneau (2019) have proposed pretraining an LM with a novel "cross-lingual LM objective" that uses parallel training data to predict masked words of either language. Edunov et al. (2019) have replaced standard word embeddings with contextual word embeddings learned by a pretrained LM. Their experiments have showed that contextual embeddings are more effective in the encoder and when fixed ("ELMo-style augmentation"). Conversely, Clinchant et al. (2019) have initialized the encoder of an NMT model with the weights of a pretrained LM network, and fine-tuned them ("GPT-2/BERT-style augmentation"), reaching similar performance, but faster convergence. Yang et al. (2020) have added the contextual embeddings of a pretrained LM as additional input features to the standard embeddings, and incorporated a dynamic switch to let the model learn how to weigh each input. Finally, the BERT-fused NMT model (Zhu et al., 2020) follows a similar idea, by adapting the architecture of the transformer network in order to have an extra self-attention layer that learns to weigh the contextual embeddings of the LM. This attention-layer is seamlessly added to both the encoder and the decoder. Given the improvement in performance achieved by the BERT-fused NMT on several datasets and the well-supported code by the authors (built on top of *fairseq*), we have decided to adopt this model in our experiments.

2.2 Backtranslation

In NMT, backtranslation (Sennrich et al., 2016; Burlot and Yvon, 2018) has become a common approach to alleviate the problem of having limited parallel data for training. It consists of first training a *target* $\rightarrow$ *source* NMT model with the available parallel corpus. Then, this model is used to translate a large number of sentences from monolingual corpora in the target language, which are usually more available than parallel corpora, to the source language. The resulting "silver corpus" is used as additional training data for the *source* $\rightarrow$ *target* NMT model, and can often help to boost the fluency of the generated translations.

However, the most effective way of using backtranslation is still an open research question. Poncelas et al. (2018) have explored different combinations of backtranslated and human-translated datasets, and have found that in their low-resource scenario a 2:1 backtranslated-to-human-translated sentences ratio is optimal; beyond that, increasing the size of the backtranslated data deteriorates the performance. Edunov et al. (2018) have shown that backtranslating by either sampling from the model or adding noise to a standard beam search can improve the final translation accuracy substantially. Burlot and Yvon (2018) have generated more natural *pseudo-source* sentences by training a generative adversarial network (GAN). Finally, Soto et al. (2020) have found that combining backtranslated data from different sources (i.e. out-of-domain data, in-domain data) and different models (i.e. rule-based, SMT, NMT) can also improve the accuracy of the final translations. In our work, we have explored using a BERT-fused NMT model for backtranslating monolingual data, expecting that the transfer learning achieved from using pretrained LM in Basque will produce better quality pseudo-source sentences.

3 Resources

All the experiments have been carried out using only the parallel and monolingual training data recommended by the organisers on the shared task website. Table 1 summarizes all the data used in our experiments.

3.1 Parallel Data

The medical terminology translation task consists on translating ICD-10 (International Clasification of Diseases) code descriptions from English to Basque. The descriptions are relatively short sentences (8 tokens on average). The organizers have provided an in-domain parallel corpus for training and validation. The blind test set contains 2,000 sentences in English.

The abstract translation task involves translating sentences of abstracts from biomedical scientific research papers. The sentence in this task are longer compared to those in the terminology task (24 tokens on average). However, for this task the organizers have not provided any in-domain parallel data for training or validation, only 375 English sentences for blind testing. Consequently, we have decided to form a small validation set from

	train	dev	test
in-domain (IO)			
ICD-10	25,900	2,000	2,000
abstracts	-	50	375
out-of-domain (OOD)			
EhuHac	550,000	-	-
QED	16,000	-	-
TED talks	5,623	-	-

(a) Parallel data.

general	
wikipedia	1.5M
biomedical	
wikipedia biomedical	8,000
hospital notes	2,000
Snomed CT	50,000

(b) Monolingual data in Basque.

Table 1: Number of sentences in each dataset.

the English-Italian biomedical abstract translation dataset provided on the website. We have selected 50 sentences in English from that dataset and translated them manually into Basque. In this way, we have managed to assemble a small, yet high-quality validation dataset in a domain similar to that of the actual task, and used it for selecting the best models for submission.

Finally, we have used out-of-domain (OOD) parallel corpora to compensate for the lack of in-domain training data. From the data provided by the organizers, we have used: the *EhuHac* dataset, which consists of translations of 136 fiction books; the *QED* dataset, which are translations of subtitles for educational videos and lectures; and the *TED talks* dataset, containing transcripts of TED talk videos.

3.2 Monolingual Data

The monolingual data have been grouped in two categories. First, we have the *general* domain texts, which include 1.5M sentences from the Basque Wikipedia. Second, we have the *biomedical* domain texts, which include a group of medical articles from the Basque Wikipedia and hospital notes written by doctors. We have applied backtranslation to generate pseudo-parallel datasets from these monolingual data. A BERT-fused NMT model has been trained over the available OOD parallel data in the reverse translation direction, and applied to translate Basque sentences to English. For more details on the training of the BERT-fused NMT model, please see Section 4.

Additionally, we have included as part of the biomedical monolingual data the subset of Basque SNOMED CT terms provided by the organizers, which have been automatically translated from English using a rule-based machine translation system. Using the IDs of the terms, we have been able to match them with the original English terms and include them as additional training data.

3.3 Pretrained BERT Models

We have explored using several different pretrained BERT LMs to include them in our BERT-fused NMT model. The pretrained BERT models have been downloaded from Hugging Face[1] :

- **bert-base-uncased** : Original BERT LM model proposed by Devlin et al. (2019). Pretrained on the BookCorpus (800M words) (Zhu et al., 2015) and the English Wikipedia (2,500M words).
- **bert-pubmed**: Pretrained over biomedical articles and journals collected from PubMed. There is no clear description of the amount of data used for pretraining. Hugging Face model name: `monologg/biobert_v1.1_pubmed`.
- **bert-mimic-pubmed**: Pretrained over biomedical articles and journals collected from PubMed and electronic health records of intensive care unit patients from MIMIC-III (Johnson et al., 2016). There is no clear description of the amount of data used for pretraining. Hugging Face model name: `adamlin/NCBI_BERT_pubmed_mimic_uncased_base_transformers`
- **bert-discharge-summaries**: Pretrained model proposed by Alsentzer et al. (2019) trained on all discharge summaries from MIMIC-III. Hugging Face model name: `emilyalsentzer/Bio_Discharge_Summary_BERT`.

Pretrained LM for backtranslation:

- **berteus-base-cased**: Pretrained LM in Basque (Agerri et al., 2020) trained over the Basque Media Corpus (BMC) (224M words). Hugging Face model name: `ixa-ehu/berteus-base-cased`.

[1] https://huggingface.co/models

4 Training and Hyperparameter Tuning

We have trained a BERT-fused NMT model (Zhu et al., 2020) with the open-source code provided by the authors[2], which is built on top of *fairseq*[3]. Following the authors recommendation, as a *warmup* step, first a standard transformer-based (Vaswani et al., 2017) NMT model has been trained over the training data. Then, this model has been used as both a baseline and to initialize the weights that the BERT-fused NMT model has in common. We have used the `transformer_iwslt_de_en` architecture as the NMT model, which consists of a 6-layer transformer network as the encoder and the decoder, with the embedding dimension set to 512 and the hidden layer dimension to 1024. Additionally, we have used the following training hyperparameters: dropout 0.1, label-smoothing 0.1, `inverse_sqrt` learning scheduler, warmup updates $4,000$, warmup initialization learning rate $1e^{-7}$, minimum learning rate $1e^{-9}$, weight decay 0.0001, BERT encoder dropout 0.5 and the Adam optimizer (Kingma and Ba, 2015). The learning rate $[0.0002, 0.00002]$ and the number of tokens per batch $[1024, 4048]$ have been tuned using the validation set. All the datasets have been lowercased and tokenized using the *moses tokenizer*. Additionally, we have learned subword units using Byte Pair Encoding (BPE) (Sennrich et al., 2015) with $10,000$ merge operations in order to reduce the vocabulary size and handle unknown words.

In the terminology translation task we have only used the in-domain ICD-10 code description data to train our models, because adding additional OOD parallel data or backtranslated data was degrading the performance of the model. This is probably likely due to the specific and structured language used in the code descriptions, which is very different from the rest of the available texts. The baseline NMT was warmed up for 50 epochs and the best model over the validation was selected. Then, the BERT-fused models was tuned for 10 more epochs.

In the abstract translation task, due to the fact that in-domain parallel data were not available, we have explored training the model with different combinations of the OOD parallel data, the ICD-10 training data and the backtranslated data. The ICD-10 data and the backtranslated biomedical data have been upsampled x5 and x10, respectively. In this task, the baseline NMT was warmed up for 30 epochs, as the training data are much larger (longer training times) and because we have seen no noticeable improvement after the 30th epoch. Like in the previous task, the BERT-fused models have been tuned for another 10 epochs over the best baseline model.

Evaluation of the models has beeen carried out using the standard BLEU metric (Papineni et al., 2002). In the case of the terminology translation task, we have also used a case-insensitive strict accuracy metric, in which an ICD-10 code description is considered correct only if it is a complete string match with the reference (no partial scores).

5 Results

5.1 Terminology Translation

In the terminology translation task (Table 3a) all the models have achieved high numerical results over the validation set ($> 73\%$ accuracy and > 88.7 BLEU). In terms of translation scores, one could say that this was an easy task and that it is almost solved. However, we would like to argue that this is not the case. Compared to other translation tasks (e.g. abstracts, news, TED talks), the space of correct translations is much smaller in the ICD-10 task since even a single-word mistake (e.g. *abscess of bursa,* ***right*** *shoulder* VS *abscess of bursa,* ***left*** *shoulder*) may result in a misunderstanding with serious consequences. Therefore, there is still margin for improvement.

On the other hand, we have observed that the BERT-fused NMT models have consistently outperformed the baseline, on average by $+1.61$ percentage points (pp) of accuracy and by $+0.7$ pp of BLEU. All pretrained BERT LMs have achieved comparable results, yet surprisingly the *bert-base-uncased* model has proved the best, despite being the only LM that had not been pretrained on biomedical data.

5.2 Abstract Translation

In the abstract translation task (Table 3b) the overall performance of the models in terms of BLEU scores has been considerably lower. This is understandable, as we did not have access to any in-domain parallel data for training. The baseline model using only the OOD parallel data has achieved an 8.67 BLEU score.

Nevertheless, we have been able to improve this result by applying our backtranslation and pretrained LMs. Just adding the backtranslated sen-

(b) Abstract translation. Average results of 3 independent runs.

Table 2: Results over the validation sets.

tences from Wikipedia (*backtranslated general* in Table 2) to the training set has improved the baseline by $+1.90$ BLEU pp, and adding the biomedical domain backtranslated sentences (*backtranslated biomedical*) and the ICD-10 parallel data has achieved a further $+2.41$ BLEU pp.

Additionally, we have observed comparable improvements with the BERT-fused NMT models, which have again consistently outperformed the baseline. In this case, the best performing pretrained LM has been the *bert-mimic-pubmed* model (14.83 BLEU) trained using only the *backtranslated general* data. This model has achieved an incremental improvement of $+6.16$ BLEU pp with respect to the baseline trained only over the OOD parallel data. It is interesting to see that adding the *backtranslated biomedical* data to the BERT-fused NMT model has not resulted in any improvement, probably because the data are more "noisy" (not grammatically well-structured sentences) and have fewer samples than the *general* backtranslations ($\sim 60,000$ vs 1.5 M).

5.3 Results over the Blind Test Sets

Table 3 shows the results achieved by our best performing models over the test sets. The translations made by our models have been submitted "blindly" and the results have been computed by the organizers. Our proposed runs for the terminology translation task have performed similarly to the validation set, achieving over 73% accuracy. On the contrary, the systems submitted to the abstract translation task have underperformed compared to the results in the validation set. We speculate this is likely due to the domain differences between our validation data and the test data. Even though both datasets are composed of translations of biomedical abstracts, they are probably coming from different databases and may have significantly different writing styles.

6 Conclusion

This work has described the translation systems submitted by the UTS_NLP team to the WMT20 Biomedical Translation shared task. The proposed systems are BERT-fused NMT models trained on a combination of in-domain parallel data, out-of-domain parallel data and backtranslations of monolingual data. The experiments have shown that combining pretrained BERT LMs and backtranslations during training has contributed to achieve considerable accuracy improvements with respect to a standard transformer-based NMT model trained only on the parallel data. Nevertheless, the official test results have shown that the performance of the systems can significantly drop if the translation domain is different. Therefore, there is still significant work to do to improve the domain adaption of these models.

Abstract

Despite the widespread adoption of deep learning for machine translation, it is still expensive to develop high-quality translation models. In this work, we investigate the use of pre-trained models, such as T5 (Raffel et al., 2019) for Portuguese-English and English-Portuguese translation tasks using low-cost hardware. We explore the use of Portuguese and English pre-trained language models and propose an adaptation of the English tokenizer to represent Portuguese characters, such as diaeresis, acute and grave accents. We compare our models to the Google Translate API and MarianMT on a subset of the ParaCrawl dataset, as well as to the winning submission to the WMT19 Biomedical Translation Shared Task. We also describe our submission to the WMT20 Biomedical Translation Shared Task. Our results show that our models have a competitive performance to state-of-the-art models while being trained on modest hardware (a single 8GB gaming GPU for nine days). Our data, models and code are available at https://github.com/unicamp-dl/Lite-T5-Translation.

1 Introduction

With the advent of deep neural networks, results in machine translation have recently improved over classical statistical strategies (Wu et al., 2016; Artetxe et al., 2018). For instance, in the Third and Fourth Conference on Machine Translation (WMT18 (Edunov et al., 2018) and WMT19 (Ng et al., 2019)), the top-performing systems for English-German and German-English competitions were based on transformers (Vaswani et al., 2017).

Transformer models are state-of-the-art architectures for Machine Translation (MT) tasks and are capable of translating the same word to different words based on the context. For instance, the word 'bank' in Portuguese can be translated to 'bench' or 'bank' depending on the context.

This work explores translation strategies using language models pre-trained on Portuguese and English corpora. More specifically, we investigate the use of **T**ext-to-**T**ext **T**ransfer **T**ransformer (T5) pre-trained model for these tasks. T5 is a text-to-text Transformer trained with a similar masked language modeling objective as BERT. In this model, all target tasks are cast as sequence-to-sequence tasks. An illustration of T5 for the English-Portuguese translation task is shown in Figure 1. The main contributions of this work are:

- We show that it is possible to train translation models that are competitive with the state of the art using few computational resources. We trained our models on a gaming desktop with an Nvidia RTX2070 GPU, i5 CPU, and 32GB RAM. In comparison, the winning submission of the WMT19 Biomedical Translation Shared Task used four NVIDIA V100 GPUs, each being approximately ten times more expensive than an RTX2070.
- We created and made public ParaCrawl 99k, a dataset of 99k sentence pairs extracted from ParaCrawl's v6.0 English-Portuguese parallel corpus (Bañón et al., 2020). This large test corpus allows researchers to evaluate their models on a general-domain translation task.
- We evaluated Google Translate on ParaCrawl 99k, allowing other researchers to compare their results to a high-quality commercial system.
- We developed an adaptation for the English pre-trained tokenizer and achieved better results on English-Portuguese translation tasks than using the tokenizer without any changes. This allows us to efficiently adapt language models to a vocabulary that was not seen during pre-training.

Online, November 19–20, 2020.

2 Related Work

The winning system of WMT'19 Biomedical competition for en-pt and pt-en translation tasks (Soares and Krallinger, 2019a) is a Neural Machine Translation (NMT) system. They used OpenNMT-py to train a transformer model on seven parallel corpora. However, differently from our models, their model was trained from scratch.

Recent works (Peters et al., 2018; Devlin et al., 2018) have shown the advantages of using pre-trained models for tasks such as question-answering and text classification. The intuition is to allow the network to use information from pre-training language representations to increase the performance on specific tasks.

Edunov et al. (2019) evaluated the use of a pre-trained encoder-decoder model for translation. Both encoder and decoder weights were tied, but they were pre-trained on different languages. This is an expensive strategy for techniques that use a trainable tokenizer, such as SentencePiece (Kudo and Richardson, 2018), because it is necessary to re-train the entire model if the vocabulary changes, as new token embeddings need to be learned.

Many commercial systems, such as Google Translate (GT) and Amazon Translate (AT), have an excellent performance on MT, but they are expensive if one needs to translate vast amounts of text. For example, we estimate that it would cost 50,000 USD to translate the 20 million sentences of ParaCrawl using GT. Unfortunately, no commercial system that we are aware of provides metric scores on public datasets that would allow us to compare their systems to ours.

3 Methods

We proposed two main strategies for translating: using a T5 model pre-trained on a Portuguese corpus and adapting the original T5 tokenizer to work with Portuguese texts.

3.1 Pre-trained Language Model

We evaluated four different scenarios: English-Portuguese translation with T5 pre-trained on a Portuguese corpus; English-Portuguese translation with T5 pre-trained on an English corpus; Portuguese-English translation with T5 pre-trained on an English corpus; Portuguese-English translation with T5 pre-trained on a Portuguese corpus.

These variations allow us to evaluate how the language used during pre-training affects the translation's performance.

3.2 Adaptation of the English tokenizer to Portuguese

Here we investigate if we can adapt to the English-Portuguese translation task a model already pre-trained on languages other than Portuguese.

We observe that using a non-Portuguese tokenizer can cause translation problems, since some Portuguese characters cannot be represented, such as letters with the tilde accent (e.g. 'ã'). To fix this issue, we propose an adaptation of the original T5 tokenizer using a pre-processing and post-processing strategy. The tokenizer's adaptation allows it to represent all possible characters in the Portuguese language.

We can divide this adaptation into two stages: *Token Completion* and *Word Regrouping*. The first stage allows the use of Portuguese special characters, such as accented vowels, whereas the second stage merges these extra tokens back to form correct words.

3.2.1 Token Completion Stage

In this step, we start adding to the tokenizer Portuguese accented vowels that were not present in it. We ended up adding fourteen of those characters, as well as the word 'não', which is the most common word in the ParaCrawl pt-en dataset.

A list of all added tokens is available in Table 1. The addition of these tokens allowed the model to learn and generate them in en-pt translation.

This is also an inexpensive method for increasing the number of words that can be represented since only the embeddings of the new tokens have to be learned from scratch. The existing token embeddings, which represent the majority of the non-Portuguese tokens, were already learned during the pre-training phase and can be reused in the fine-tuning phase.

We show in Table 2 some encoding and decoding examples after adding tokens to the tokenizer.

ì ò Á Í Ó Ú í ú Â Ê Ã Õ ã õ não

Table 1: List of tokens added to the T5 tokenizer by our adaption method.

3.3 Word Regrouping Stage

When adding tokens directly to the tokenizer, the HuggingFace's (Wolf et al., 2019) SentencePiece

eu gosto de arroz → eu gosto de arroz
eu não como → eu n ? o como
indignação completa → indignaç ? o completa
Tokenizer with additional Port. tokens
original → after encoding/decoding
eu gosto de arroz → eu gosto de arroz
eu não como → eu não como
indignação completa → indignaç ã o completa

Table 2: Comparing tokenizer results before and after adding the Portuguese tokens.

implementation used in our work interprets the result as a new complete token, i.e., not part of a word. For example, the word ’pão’ is broken into three different tokens ’p’ ’ã’ ’o’.

In this step, we regroup the added tokens of vowels with accents separated erroneously by the tokenizer. We find in the translated text all tokens added in the Token Completion step, and merge them with their neighboring words.

In Figure 2, we illustrate our algorithm.

4 Datasets

We trained our models using six different datasets, and we evaluate our system on two datasets: the WMT19 Biomedical Translation Task dataset and a subset of 99,000 sentence pairs of the ParaCrawl dataset. We also present the results of our submission to the WMT20 Biomedical Translation Task competition.

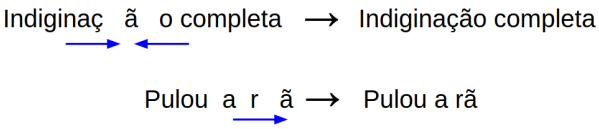

Figure 2: An example of separated tokens merged back into a single word. Our algorithm searches for an isolated special token (in this case, ’ã’) and merges it with its neighbors. It can be merged at the beginning, middle, or end of a sentence.

4.1 Training Datasets

We have two different strategies for training our models depending on the test datasets. For the evaluation on the ParaCrawl dataset, we only trained the models on ParaCrawl data. ParaCrawl is a public parallel corpus of many European languages available online. Its v6.0 version contains approximately 20M English-Portuguese sentence pairs. Due to our small computational budget, we randomly selected approximately 5M pairs for training.

For WMT19 and WMT20 Biomedical Translation Tasks, we train our models on the ParaCrawl dataset as well as on the following datasets, which are mostly of the same domain as WMT’s Biomedical data:

- EMEA Corpus (Tiedemann, 2012): A parallel corpus of European Medicines Agency documents.
- CAPES Parallel Dataset (Soares et al., 2018b): A parallel corpus of theses and dissertations abstracts collected from the CAPES website.
- Scielo Dataset (Soares et al., 2018a): A parallel corpus of scientific articles collected from

SciELO.

- JRC-Acquis (Steinberger et al., 2006): A parallel corpus of European Union (EU) documents in all official EU languages.

- Biomedical Domain Parallel Corpora (Névéol et al., 2018): A repository of the challenge that contains links to different parallel corpora. We used the Medline, Scielo, and ReBEC training datasets.

Besides being of the same domain as WMT's Biomedical task, an advantage of these datasets over ParaCrawl is that they are in Brazilian Portuguese, such as most of WMT's Biomedical data. The number of sentence pairs used for training from each dataset is shown in Table 3.

Corpus	Sent. Pairs
EMEA	1,082,144
CAPES	1,157,610
Scielo	2,828,916
JRC-Acquis	1,236,846
Biomedical Domain Corpora	331,937
Total	**6,637,453**

Table 3: Number of sentence pairs of each domain-specific dataset used to train our models for the WMT19 and WMT20 Biomedical tasks.

4.2 Testing Datasets

We created a general-domain test set from the ParaCrawl dataset. We begin by randomly selecting 128,000 sentence pairs from its 20M pairs. ParaCrawl is originally deduplicated, but similar sentences still might exist in our split of the training and test sets. Thus, we apply as stricter deduplication process to increase the quality of our test set. To increase the speed in verifying similarity of sentence pairs, we used MinHash and Locality-Sensitive Hashing (LSH) (Rajaraman and Ullman, 2011) to compare sentences of training and test datasets. We set a Jaccard similarity threshold to 0.7, i.e., all sentences with similarity greater than 0.7 were discarded from the test set. LSH found 28,913 sentences in the test set with a similarity score above 0.7 of sentences in the training set. The final test set ended up having 99,087 sentence pairs, which we called ParaCrawl 99k test set. This dataset and its corresponding translations using GT are available in our GitHub repository.

We also evaluated our system on the WMT19 Biomedical Shared Task test set. This is a dataset composed of approximately 500 parallel sentences of Medline abstracts.

Finally, we submitted our results to the WMT20 Biomedical Shared Task competition. The WMT20 test set has 544 parallel sentences for the English-Portuguese translation task and 498 sentences for the Portuguese to English task.

5 Experiments

We conducted several experiments using different configurations of T5. We divided the experiments into two groups: model hyperparameter optimization and different pre-training studies. All experiments were performed on a desktop computer with an Nvidia 8GB RTX 2070 Super, 32 Gb RAM memory, and a 4-core Intel processor running on Ubuntu 18.04. We used PyTorch (Paszke et al., 2017), HuggingFace Transformer, and Pytorch-Lightning (Falcon, 2019) frameworks to train and evaluate our models.

5.1 Model Hyperparameter Optimization

We tuned the hyperparameters using the original T5 checkpoint available in the HuggingFace library. This model was pre-trained on a corpus whose majority of documents were in English with a small proportion of German, French, and Romanian documents. We first conducted a small training using 100k sentence pairs and evaluated on another 50k sentence pairs to determine some hyperparameters of the T5 model, such as batch size and the maximum length of tokens in the source and target sentences. We also evaluated the optimizer and found the best convergence with the AdamW Optimizer (Loshchilov and Hutter, 2017). All hyperparameters used are in Table 4. With this configuration, we evaluated the performance of adding Portuguese-only characters to the tokenizer in comparison to using the original T5 tokenizer. The results are available in Table 5. Our proposed tokenizer adaption resulted in an improvement of almost 5 BLEU points over the original tokenizer in the en-pt translation task. All BLEU scores reported in this paper were generated using SacreBLEU (Post, 2018) with "intl" tokenization.

After finding these hyperparameters, we analyzed the trade-off between model sizes in a subset of the ParaCrawl dataset of 1M sentence pairs and evaluated them in a 150k sentence subset. We did

Hyperparameters	Values
Batch Size	256
Source Sequence Length (SSL)	96
Target Sequence Length (TSL)	160
Learning Rate	$5 \cdot 10^{-3}$
eps	$1 \cdot 10^{-5}$

Table 4: Hyperparameters used for training the models.

Translation Type	BLEU
Original T5 tokenizer	31.15
+ Portuguese characters	35.95 (+4.8)

Table 5: Effects in performance of using our adaption of the original T5 tokenizer to the English-Portuguese translation task. Numbers are from ParaCrawl's 99k en-pt test set.

not use any sentence from the test set. The results of this analysis are reported in Table 6. We trained the T5-small and T5-base models with different epoch sizes. Training 3 epochs of T5-small takes almost the same time as training one epoch with a T5-base model.

The performance would possibly increase if we used large models such as T5-large, T5-3B, or T5-11B. However, we could fit only the T5-base model in our 8GB GPU. We used batch accumulation to achieve batches of size 256 as the T5-small can only handle batch size 4 in 8GB. Thus, one of the contributions of this work is to show that it is possible to train translation models that are close to the state of the art on a relatively inexpensive hardware.

We also conducted experiments changing SSL and TSL lengths. We found that it is not necessary to set large TSL and SSL values, e.g., 256 for both, but it is essential to choose a value that can represent the distribution of target and source sequences. In later sections, we conduct experiments with TSL and SSL 140 and 160, respectively, since 99.8 % of our training dataset is shorter than these values.

All experiments in the following sections using Tokenizer's Adaptation Steps (3.2) were performed using the best pre-processing and post-processing strategies presented in Table 6.

5.1.1 Pre-training Studies

We also evaluated the effects of pre-training the model in a corpus of the same language of the target language. The intuition here is that it would be easier for the model to learn the target language than having previous knowledge of the source language. Since the tokenizer mainly has tokens of one of the two languages, it is better to have a smaller quantity of tokens to learn. This is because, if the SentencePiece tokenizer does not have the word in its vocabulary, it will use subtokens to form the original word. For example, the sentence 'They like to drink coconut water' is represented by six tokens in English SentencePiece and thirteen tokens in Portuguese SentencePiece. We are not evaluating here the possibility to train the pre-training model from scratch with both languages together, as it is not possible with our modest hardware setup.

Translation Type	Sacre BLEU
Adding Top 25 words in Port. + T5-small + 3 epochs	43.03
Adding tokens of Table 1 in Port. + T5-small + 3 epochs	43.48
Adding tokens of Table 1 in Port. + T5-base + 1 epoch	**44.52**

Table 6: Effects in performance of different strategies for adapting the original T5 tokenizer to Portuguese. Numbers are from our dev set of ParaCrawl.

For the Portuguese pre-trained model, we used PTT5-base model (Carmo et al., 2020) with Portuguese tokenizer. PTT5 was pre-trained on BrWAC, a large corpus of Brazilian Portuguese webpages. PTT5 started training using T5's official published weights as initial weights, so it also uses English learning in its model. For the English pre-trained model, we used the Huggingface implementation of T5 with its default tokenizer, which is based on SentencePiece.

In Table 7, we compare both models with Google Translate in the ParaCrawl 99k test set. Both models perform similarly in the Portuguese-English translation task, but the Portuguese pre-trained model gives a better result than the English pre-trained model in the English-Portuguese translation task. We are on par with Google Translate on en-pt, but a few BLEU points below on pt-en.

6 WMT19 and WMT20 Results

We now evaluate our models on the WMT19 Biomedical Translation Task and the results of our best models and official submission to the WMT20 Biomedical Translation Task.

	pt-en	en-pt
Google Translate API	51.20	45.17
Ours - English pre-training	46.49	44.56
Ours - Portuguese pre-training	46.35	45.44

Table 7: BLEU comparison between GT and our approach in Paracrawl 99k test set.

In Table 8, we show WMT19 results of our models as well as the winning submission of WMT19 Biomedical tasks (Soares and Krallinger, 2019b) and the MarianMT (Junczys-Dowmunt et al., 2018) implementation available on the HuggingFace's Transformer Library.[1] MarianMT's translation uses a multilingual Romance model, which is only possible to set the target language. This explains MarianMT's low performance on Portuguese to English translation since the model has to infer that the input sentence is in Portuguese. Models pre-trained on Portuguese obtained the best performance in both translation tasks. Notably, we achieved an improvement of +6.31 BLEU points in the English to Portuguese translation task by using the Portuguese pre-trained model and +9.75 with an increase of target and source sequence lengths. We also obtained an improvement of +0.62 in the Portuguese to English translation task using the Portuguese pre-trained model and +2.27 when increasing target and source sequence lengths.

We believe that the improvement of Portuguese pre-training models is associated with PTT5's training strategy that uses English pre-trained weights as initial weights. The intuition is that PTT5 carries information from the English model too.

The results for WMT20's challenge are in Table 9. Our submission is 2.17 BLEU points below the winning team in Portuguese-English, but it is 4.48 BLEU points higher than the baseline. For the English-Portuguese task, our results are below the baseline. That can be attributed to not using the Portuguese pre-trained model, which was not available at the time of our submission. As noted above, we achieved a large improvement on WMT19 when we switched from the English to the Portuguese pre-trained model. Therefore, we assume that a Portuguese pre-trained model would obtain superior results to the baseline on WMT20.

We also evaluated our Portuguese pre-training models with the best participants submissions of the WMT20 Biomedical Shared Task. The results of this comparison are in Table 10 and are slightly different from Table 9 since we are using SacreBLEU as the evaluation script. Our best translation models are 1.3-1.5 BLEU points bellow the winning submission (Sheffield) in both translation directions (pt-en and en-pt).

7 Conclusions and Future Work

We show that it is possible to develop English-Portuguese translation models close to the state of the art using modest hardware. Despite not reaching the same level of performance of Google Translate on pt-en, the fact that our system was devel-

oped mostly by the first author on its personal computer shows that implementing high-quality machine translation systems has become possible for anyone, including small companies and research labs. We also cannot guarantee that Google did not use our testing data for training.

We presented our submission strategies for the WMT20 Biomedical Translation Shared Task using a T5 model. We show that a simple adaption of the original T5 tokenizer to the Portuguese language largely improves the translation quality and does not require any further pre-training, which is expensive. However, we achieve the best results with models pre-trained on Portuguese.

As directions for future work, we plan to experiment with larger models and models pre-trained on both Portuguese and English languages simultaneously, as recent work showed that this a successful strategy (Wu et al., 2016; Arivazhagan et al., 2019). We believe that we could improve the translation results with larger and more complex models (Lepikhin et al., 2020).

The ADAPT's Submissions to the WMT20 Biomedical Translation Task

Prashanth Nayak, Rejwanul Haque and Andy Way
The ADAPT Centre, School of Computing
Dublin City University, Dublin, Ireland
firstname.lastname@adaptcentre.ie

Abstract

This paper describes the ADAPT Centre's submissions to the WMT20 Biomedical Translation Shared Task for English-to-Basque. We present the machine translation (MT) systems that were built to translate scientific abstracts and terms from biomedical terminologies, and using the state-of-the-art neural MT (NMT) model: Transformer. In order to improve our baseline NMT system, we employ a number of methods, e.g. "pseudo" parallel data selection, monolingual data selection for synthetic corpus creation, mining monolingual sentences for adapting our NMT systems to this task, hyperparameters search for Transformer in low-resource scenarios. Our experiments show that systematic addition of the aforementioned techniques to the baseline yields an excellent performance in the English-to-Basque translation task.

1 Introduction

The ADAPT Centre participated in the Biomedical Translation Shared Task of the Fifth Conference of Machine Translation (WMT20). This task is about evaluating systems on the translation of documents from the biomedical domain. The test data consists of biomedical abstracts and terminologies. The task addresses a number of language pairs, and we participated in the English-to-Basque translation task. To make the readers familiar with the biomedical translation task and to understand the challenges of this task, we show a couple of examples from the blind test set and two terminological expressions from terminology test set in Table 1.

For building our MT systems we used the Transformer model (Vaswani et al., 2017). Our strategies to build the competitive MT systems for the task roughly include (i) pseudo in-domain parallel and monolingual data selection, (ii) augmenting training data (Sennrich et al., 2016a; Zhang and Zong, 2016; Burlot and Yvon, 2018; Poncelas et al., 2018; Caswell et al., 2019; Chen et al., 2019), (iii) mining monolingual sentences to adapt our NMT systems to the task, and (iv) finding the optimal hyperparameter configuration for Transformer in this low-resource settings.

(1) No cardiovascular risk factor differences were found in terms of age.
(2) Congenital tumors show a different pattern than tumors in other pediatric ages.
(3) Open bite of thyroid gland, sequela
(4) poisoning by oxytocic drugs, undetermined, subsequent encounter

Table 1: Sentences ((1) and (2)) from the blind test set and sample terminological expressions ((3) and (4)).

The remainder of the paper is organized as follows. In Section 2, we present our methods, and Section 3 details of the data sets used. Section 4 presents the results and discussions, while Section 5 concludes our work with avenues for future work.

2 Our Approaches

2.1 Selecting pseudo In-domain Parallel Sentences

The shared task organisers released parallel training data with a limited number of in-domain examples (only 24,247). The organisers also provided the participants with moderate-sized three out-of-domain corpora (totalling to approximately 770K bitexts). In an attempt to improve the quality of our baseline MT systems, we extracted those sentence-pairs from the out-of-domain corpora that are similar to the styles and domain of the texts we aim to translate, and were used in system building.

2.1.1 Selection using Bilingual Cross-Entropy Difference

We followed the state-of-the-art sentence selection approach of Axelrod et al. (2011) that extracts pseudo in-domain sentences from out-of-domain

Proceedings of the 5th Conference on Machine Translation (WMT), pages 841–848
Online, November 19–20, 2020.

corpora using bilingual cross-entropy difference over each side of the corpus (source and target). The bilingual cross-entropy difference is computed by querying in- and out-of-domain (source and target) language models.

2.1.2 Selection using Terminology

Terms are usually indicators of the nature of a domain and plays a critical role in domain-specific MT (Haque et al., 2020). Sentences that contain domain terms are likely to be a domain text. However, a ambiguous term could have more than one potential meaning. As an example of lexical ambiguity, 'cold' has several possible meanings in the Unified Medical Language System Metathesaurus (Humphreys et al., 1998) including 'common cold', 'cold sensation' and 'cold temperature' (Stevenson and Guo, 2010). We can see that 'cold' could have very different meanings depending on the context in which it appears. Moreover, a polysemous term (e.g. 'cold') could have many translation equivalents in a target language.

In our second sentence selection approach, we mine those sentences from large out-of-domain or general domain corpus that contain domain terms. As pointed out above, an extracted sentence that contain a domain term may not represent the desired domain; however, the training examples that include such extracted sentences may play crucial role in minimising lexical selection errors as far as terminology translation is concerned (Haque et al., 2020).

To this end, we exploit the approach of Rayson and Garside (2000) and Haque et al. (2014, 2018) in order to automatically identify terms in the in-domain texts. The idea is to identify those words which are most indicative (or characteristic) of the in-domain corpus compared to a reference corpus. Haque et al. (2014, 2018) used a large corpus which is generic in nature as a reference corpus. We adopted their approach and used a large generic corpus in order to identify terms in the in-domain source (English) and target (Basque) corpora. Given the lists of source and target terms, we mine sentences independently from the source- and target-sides of the out-of-domain bilingual corpus. We select those sentence-pairs from the out-of-domain bilingual corpus whose source or target sides contain at least one domain term.

2.2 Training Data Augmentation

The data augmentation methods in NMT (Sennrich et al., 2016a; Zhang and Zong, 2016; Burlot and Yvon, 2018; Bogoychev and Sennrich, 2019; Caswell et al., 2019; Chen et al., 2019), which usually employ the unlabeled monolingual data in addition to limited bitexts, can positively impact translation quality and are very popular among the MT developers and researchers (Barrault et al., 2019). In other words, use of synthetic data to improve a NMT system is nowadays a common practice, especially in the under-resource scenarios.

The synthetic training data whose source-side sentences are original is more effective for domain adaptation. The learning method that uses such training data is called self-training (Ueffing et al., 2007). The synthetic training data whose target-side is original is more effective for domain text translation and generation of fluent translations (Sennrich et al., 2016a). Many studies (e.g. Chen et al. (2019); Bogoychev and Sennrich (2019)) have shown that self-training and back-translation can be complementary to each other.

In this task, in order to improve our baseline Transformer models, we augmented our training data with both the target- and source-original synthetic data. As in Caswell et al. (2019), in order to let the NMT model know that the given source is synthetic, we tag the source sentences of the synthetic data with the extra tokens.

Iterative generation and training on synthetic data can yield increasingly better NMT systems, especially in low-resource scenarios (Hoang et al., 2018; Chen et al., 2019). Since our baseline source-to-target and target-to-source MT systems are already excellent in quality, those were used to translate the monolingual data.

As in Section 2.1, we extract those sentences from large monolingual data that are similar to the styles of texts we aim to translate. We used the extracted pseudo in-domain monolingual sentences to produce the source- and target-original synthetic bitexts. As for the NMT training, we believe that synthetic parallel data created from pseudo in-domain sentences could be the better alternatives than those selected randomly.

2.2.1 Selection using Language Model Perplexity

Sentences of a large monolingual corpus similar to the in-domain sentences when selected based on the perplexity according to an in-domain language model were found to be effective in MT (Gao et al., 2002; Yasuda et al., 2008; Foster et al., 2010; Axelrod et al., 2011; Toral, 2013). Accordingly, we select "pseudo" in-domain sentences from a large monolingual data based on their perplexity scores accoring to the in-domain language model, which

are then translated to form synthetic training data.

2.2.2 Selection using Terminology

We mine "pseudo" in-domain sentences from large monolingual corpora following the method described in Section 2.1.2. We select those sentences from the monolingual corpus that contain at least one domain term. For mining monolingual sentences we create an efficient Trie structure given the large monolingual data. The idea is to store indices of the sentences (i.e. we restrict this number to 50) for each *n*-gram (upto trigram) of the corpus. Given the domain terms of the in-domain text, we can instantly retrieve the sentences from corpus.

2.3 Mining Sentences for Fine-tuning

Chinea-Ríos et al. (2017) demonstrated that in case of specialised domains or low-resource scenarios where parallel corpora are scarce sentences of a large monolingual data that are more related to the test set sentences to be translated could be effective for fine-tuning the original general domain NMT model. They select those instances from large monolingual corpus whose vector-space representation is similar to the representation of the test set instances. The selected sentences are then automatically translated by an NMT system built on a general domain data. Finally, the NMT system is fine-tuned with the resultant synthetic data. In a similar line of research, it has also been shown that an NMT system built on general domain data can be fine-tuned using just a few sentences (Farajian et al., 2017, 2018; Wuebker et al., 2018; Huck et al., 2019).

2.3.1 Mining Source Language Monolingual Sentences

Since English–Basque is a low-resource language-pair and have a little amount of bitexts pertaining to the targeted domain (biomedical), we followed Chinea-Ríos et al. (2017) in order to mine those sentences from large monolingual data that could be beneficial for fine-tuning the original NMT models. In other words, we followed the method described in Section 2.1.2 in order to extract sentences form large monolingual corpus. As above, we identify terms in the test set (i.e. scientific abstracts of Medline) to be translated. As for the sub-task where the task is to translate the domain terms from English to Basque, we observed that many terminological entries are in fact a part of full sentences (e.g. 'person on outside of car injured in collision with pedestrian or animal in traffic accident, initial encounter') and contain general domain tokens. Therefore, we treat the terminological entries as normal sentences and translate them similarly to the Medline abstracts.

In addition to following the standard terminology extraction methods of Haque et al. (2014, 2018) who used a large corpus which is generic in nature as a reference corpus, in a second setup, we used either side of the authentic training bitexts on which the NMT systems were trained as the reference corpus. The intuition is to extract those terminological expressions from the test set that do not occur or rarely occur in the training data and are more indicative of the test corpus. We merged the two sets of terms extracted following the two setups above. Given the resultant list of terms, we mine sentences from monolingual corpus. The source sentences that have been mined are translated with the MT system in order to form synthetic bitexts to be used for adaptation.

2.3.2 Mining Bitexts

Farajian et al. (2017, 2018) exploit the similarity between the source sentences of the training examples and each test sentence and update their generic NMT model on-the-fly on a set of most similar training examples. Like them, we mine training examples form the bilingual training corpus. However, unlike them, our extraction process is driven by the domain terms appearing in the test set which is to be translated. In sum, we follow the bilingual sentence-pair extraction method described in Section 2.1.2 given the test set. For extraction we considered both in-domain and out-of-domain parallel corpora. The extracted bitexts are merged with the generated synthetic segment-pairs above (cf. Section 2.3.1). As in Chinea-Ríos et al. (2017), the best NMT system is finally fine-tuned on the combined train data.

2.4 Tuning Hyperparameters for Transformer

The NMT systems are Transformer models (Vaswani et al., 2017). To build our NMT systems, we used the MarianNMT (Junczys-Dowmunt et al., 2018) toolkit. The tokens of the training, evaluation and validation sets are segmented into sub-word units using Byte-Pair Encoding (BPE) (Sennrich et al., 2016b). We found that performance of the Transformer model more-or-less similar whether BPE is applied individually or jointly on the source and target languages. We kept the former setup, i.e. BPE is applied individually on the source and target languages. Recently, Sennrich and Zhang (2019) demonstrated that commonly used hyperparameter configuration do not lead to the best results in

low-resource settings. Accordingly, we carried out a series of experiments in order to find the best hyperparameter configuration for Transformer in our low-resource setting. In particular, we played with some of the hyperparameters, and found that the following configuration lead to the best results in our low-resource translation settings: (i) the BPE vocabulary size: 6,000, (ii) the sizes of the encoder and decoder layers: 4 and 6, respectively, and (iii) learning-rate: 0.0003. The models are trained with the Adam optimizer (Kingma and Ba, 2014), reshuffling the training corpora for each epoch. As for the remaining hyperparameters, we followed the recommended best setup from (Vaswani et al., 2017). The early stopping criteria is based on cross-entropy; however, the final NMT system is selected as per the highest BLEU score on the validation set. The beam size for search is set to 12. We make our final NMT model with ensembles of 8 models that are sampled from the training run.

3 Data Used

This section presents the data sets which were used for system building. We used the bilingual data provided by the WMT20 Biomedical Shared Task organisers only. As for English monolingual corpus, we used all in-domain texts released by the organisers including the English side of the bilingual corpora of the language-pairs. As for Basque monolingual data, organisers provided us with a tiny set of in-domain sentences. Since the participants are allowed to use external data, we used the CommonCrawl[1] corpus for Basque. Table 2 presents the corpus statistics. The out-of-domain

Bilingual			
in-domain	sentences	words (EN)	words (EU)
train	24,247	201,583	205,334
development	2,000	16,324	16,667
out-of-domain	770,273	12,637,438	11,289,811
Monolingual (sentences)			
	in-domain	CommonCrawl	
Basque	41,151	12,583,122	
English	9,015,051		

Table 2: The Corpus statistics.

parallel corpora for the English-to-Basque task are from three different sources (i.e OPUS (Tiedemann, 2012), IWSLT 2018 (Jan et al., 2018) and WMT16 IT Shared task (Bojar et al., 2016)). We merged segment-pairs of all three data sources, and after applying cleaning scripts to the data we are left with 770K parallel segments (cf. fifth row of Table 2).

[1] https://commoncrawl.org/

Since the size of English in-domain monolingual corpus is reasonably big, we did not use any English out-of-domain data for system building. In order to perform tokenisation for English and Basque texts, we used the standard tool of the Moses toolkit. The development data released by the task organisers contains 2,000 sentences (cf. fourth row of Table 2), out of which 1,000 sentences are used as the test set. The remaining sentences of the development set are used for validation.

4 Experiments and Results

This section presents the performance of our MT systems in terms of the automatic evaluation metric BLEU (Papineni et al., 2002). Additionally, we performed statistical significance tests using bootstrap resampling methods (Koehn, 2004).

4.1 The Baseline MT System

First, we build an English-to-Basque NMT system on the in-domain parallel corpus (cf. Table 2) only, and we refer the MT system as Base. Note that size of the original test set is 1,000 and its sentences were randomly sampled from development set released by the organisers (cf. Section 3). We evaluate Base on the original test set and report its BLEU score in Table 3. As far as the BLEU score on original test set is concerned, it is excessively high. When we looked at the translations, we saw that they are nearly perfect. We

	BLEU
Original test set (1,000)	91.12
test set (200)	47.14

Table 3: The BLEU scores of the basline NMT system (Base).

checked how similar the original test set sentences is to the in-domain training set sentences. For this, we apply fuzzy string matching with a threshold of 80%, and used SimString[2] algorithm (Okazaki and Tsujii, 2010) for search. We found that the number of the non-matching sentences of the test set is 200 (out of 1,000), and same of the development set is 194 (out of 1,000). This indicates that the test and development sets sentences are very similar to those of the training set. The scores on the original test and development sets could be misleading for the evaluation and validation of MT systems. Therefore, for fair evaluation we used the non-matching sentences as the test set (200).

[2] http://www.chokkan.org/software/simstring/

Note that the BLEU scores reported in this paper are on this test set. The BLEU scores of Base on the test set is reported in the last column of Table 3. Similarly, we used the non-matching sentences of the original development set as the development set (194).

4.2 The Improved MT Systems

We applied the pseudo in-domain bilingual sentence selection strategies described in Section 2.1 to the out-of-domain bilingual data (cf. Table 2). We first apply the bilingual cross-entropy difference (BCED) measure described in Section 2.1.1. The so-called pseudo in-domain parallel sentences that were extracted from the out-of-domain data were appended to the in-domain training data, and the BLEU scores of the NMT systems trained on the combined training data are shown in the top rows of Table 4. As can be seen from the table, when the size of pseudo in-domain data is 100K, the MT system (Base+BCED-100K) produces 50.68 BLEU on the test set (a 3.54 BLEU points corresponding to 7.5% relative gain over the Base).

	BLEU
Base+BCED-100K	50.68
Base+BCED-150K	49.02
Base+BCED-200K	47.38
Base+BiTerm	52.19
Base+BiTerm+BCED-100K	53.07

Table 4: The BLEU scores of the NMT systems trained on the in-domain added with the pseudo in-domain training data.

Next, we apply our second method (cf. Section 2.1.2), and the pseudo bilingual corpus extracted following this method contains 294,998 segment-pairs. As above, we append this data to the in-domain data. The BLEU score of MT system (Base+Term) built on the combined data is reported in Table 4. We see from the table that this strategy provides us a 5.05 BLEU points (corresponding to 10.7% relative) gain over the baseline.

When we merge these two pseudo in-domain parallel data with the real in-domain data and train the MT model on the combined data, we further achieved a moderate BLEU gain over the baseline (a 5.95 BLEU points corresponding to 12.6% relative gain). We used this MT system (Base+BiTerm+BCED-100K) for further experimentation, which, from now on, is referred to Base2.

	BLEU
Base2+BT1	52.72
Base2+BT2	53.65
Base2+BT3	53.70
Base2+FT1	52.02
Base2+FT2	51.45
Base2+BT3+FT1	52.76

Table 5: The BLEU scores of the NMT systems trained on augmented training data.

As pointed out above, we augment our bilingual training data with forward and back-translated synthetic data. The BLEU scores of the MT systems trained on the augmented training data are reported in Table 5.

First, we create a synthetic train data by back-translating the tiny monolingual in-domain training data, and the BLEU score of the MT system built on the training data that includes this synthetic data is shown in the second row of Table 5 (i.e. Base2+BT1). This data could not improve Base2.

We extract 275,125 sentences from Basque monolingual data following the method described in Section 2.2.2 (i.e. using the list of terminology extracted from in-domain corpus), and created synthetic bitexts as above. We further add these synthetic bitexts to the training data.[3] The BLEU score of the MT system trained on this data (Base2+BT2) is shown in Table 5. This MT system brings about a 0.58 BLEU points improvement over Base2, and this time, the improvement is not statistically significant.

We further select top 200K target sentences (Basque) based on perplexity scores following the method described in Section 2.2.1. Note that many extracted sentences overlap with those extracted using terminology. We obtained the similar BLEU score on the test set when the synthetic data that is created from this data is further appended to training data (i.e. Base2+BT3).

As mentioned above, we have large monolingual in-domain corpus for English (cf. Table 2). Therefore, we directly used the in-domain English sentences for self-learning. We carried out a number of experiments with adding the source-original synthetic sentences with the original training data, e.g. Base2+FT1 and Base2+FT2 refer to 200K and 1M synthetic segment-pairs. We started doing forward translation with the Medline text. The self-training strategy could not surpass the best-performing MT

[3] Note that this training data refers the one that corresponds to Base2+BT1.

system, i.e. Base2+BT3.

4.3 Fine-tuning the best NMT systems

This section presents the MT systems that were prepared by the adaptation technique described in Section 2.3. We select Base2+BT3 and Base2+BT3+FT1 for adaptation. Following the method described in Section 2.3.1 we mine the source monolingual sentences from the large English in-domain corpus given the list of terms extracted from the test set. Then, synthetic data is created by translating the source sentences by the source-to-target MT systems. We follow the method described in Section 2.3.2 and mine sentence-pairs from in- and out-of-domain bitexts given the list of terms extracted from the test set. The synthetic data and extracted sentence-pairs are merged to form training data for adaptation. Finally, the best MT systems were fine-tuned on this training data. The BLEU scores of the adapted MT systems on the test set are reported in Table 6. When we compare the original MT systems reported in Table 5 with the adapted MT systems, we see that (i) the adapted version of Base2+BT3 produces a 1.1 BLEU points (corresponding to 2.05% relative) improvement over Base2+BT3, and (ii) the same of Base2+BT3+FT1 produces a 1.51 BLEU points (corresponding to 2.87% relative) improvement over Base2+BT3+FT1. The improvements are statistically significant.

	BLEU
Base2+BT3	54.80
Base2+BT3+FT1	55.21

Table 6: The BLEU scores of the adapted MT systems.

As above, we create the adapted MT systems for the blind test set and terminology. Then, we translate the blind test set sentences and terminological entries with the adapted MT systems (Base2+BT3, Base2+BT3+FT1). For our third submission we chose a non-adapted MT system, Base+BiTerm+BCED-100K (cf. Table 4).

In Table 7, we show the BLEU scores of MT systems on the blind test sets. As for abstract translation, Base+BiTerm+BCED-100K is found to be the best system. This system earned us the third position in the task. For the evaluation of terminology translation, in addition to BLEU, the organisers used the accuracy metric which relies on strict matches between ground truth and predictions (cf. Table 7). Base2+BT3 and Base2+BT3+FT1 produce the best BLEU and accuracy scores, respectively, on the terminology test set. Our systems earned us the second position in the terminology translation task.

		BLEU
Base+BiTerm+BCED-100K		**8.67**
Base2+BT3 (adapted)		8.25
Base2+BT3+FT1 (adapted)		8.08
	Acc.	BLEU
Base+BiTerm+BCED-100K	0.73	70.83
Base2+BT3 (adapted)	0.75	**72.39**
Base2+BT3+FT1 (adapted)	**0.76**	71.79

Table 7: Performance of our submitted MT systems in the abstract (top 3 rows) and terminology (bottom 3 rows) translation tasks.

5 Conclusion

This paper presents the ADAPT system description for the WMT20 Biomedical Translation Shared Task. We participated in the English-to-Basque translation task. The task is to translate scientific abstracts and terms from biomedical terminologies. We aimed to build a competitive translation system for this task. For this, we applied various strategies, e.g. selecting monolingual and bilingual texts that are similar to the in-domain data, mining monolingual sentences, applying adaptation technique for adapting the neural MT models to the task, hyperparameters search. We found that our strategies to improve the baseline MT system were effective and yields excellent performance.

This paper demonstrated a novel adaptation approach for translating domain texts. This method is found to be effective in this translation task. In the future, we aim to test the on-the-fly adaptation method (Farajian et al., 2017, 2018) to translate domain texts.

Abstract

This paper reports system descriptions for FJWU-NRPU team for participation in the WMT20 Biomedical shared translation task. We focused our submission on exploring the effects of adding in-domain corpora extracted from various out-of-domain sources. Systems were built for French to English using in-domain corpora through fine tuning and selective data training. We further explored BERT based models specifically with focus on effect of domain adaptive subword units.

1 Introduction

In this paper, we present Neural Machine Translation (NMT) systems developed by Fatima Jinnah Women University for participation in WMT20, Biomedical shared Translation task. The systems are developed for translating English/French (EN/FR) in both directions for biomedical domain using fairseq (Ott et al., 2019) and BERT (Devlin et al., 2018). To tackle in-domain corpus shortage challenge, selective data training and fine tuning are explored. We focused our submission on investigating the effects of adding in-domain corpora extracted from out-of-domain sources of various domains, objective was to study the effect of domain non-relatedness in schemes involving data selection through information retrieval or any sentence selection method. We further explored BERT based models specifically with focus on effect of domain adaptive subword units.

Neural Machine Translation systems have shown substantial growth with the ongoing introduction of new tool kits and training techniques to support developers in training models (Bahdanau et al., 2014; Wu et al., 2016). But the availability and cleaning of domain related corpora to achieve terminology advantage and fluency is still a challenge for many researchers as the accessible corpora is relatively small in size and comparatively noisy. In order to improve in-domain NMT systems, out-of-domain data is used and the most common method is to fine tune pre trained NMT models on in-domain data and selective data training (Hira et al., 2019).

Our last years submission presented promising results using selective data training incorporating data retrieved from News Commentary corpus by building two layered RNN systems. We extend our framework to study the quality of retrieved sentences from 3 more parallel corpora. We did not restrict to parallel data for mining biomedical sentences, rather this year we included monolingual data in our framework and studied the effect of using Back Translations (BT) in our framework. For building NMT models we explored subword units and report the results on using pre-trained BERT fused embedding.

2 Data Selection Architecture

Improving translation quality is a challenging task especially for domains where enough in-domain parallel corpus is not available to train a good translation system. To overcome data scarcity problem, several data selection techniques have been proposed over the years including information retrieval (IR) (Rauf and Schwenk, 2011), edit distances (Wang et al., 2013), cross entropy measures (Axelrod et al., 2011) and several others. We used the approach of relative query sentences using information retrieval to retrieve matching sentences from general domain corpora.

French-English is not a resource scarce language pair and has numerous parallel corpora available for various domains. There exist sizable corpus for the Biomedical domain to train the initial systems, but the great difference of terminologies and language jargon in various sub domains makes it challenging as the results of previous years bio med-

Proceedings of the 5th Conference on Machine Translation (WMT), pages 849–856

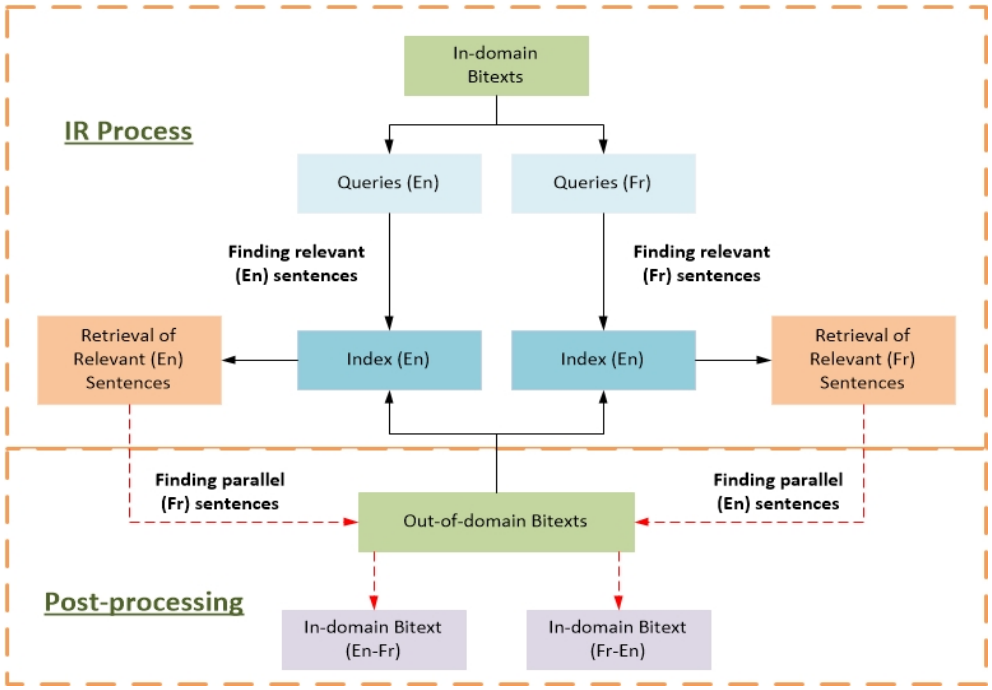

Figure 1: Data selection Architecture.

ical tasks indicate. Parallel corpora extracted from "other" easily available corpora, like comparable corpora and monolingual corpora do help improve MT performance (Abdul-Rauf and Schwenk, 2009; Abdul-Rauf et al., 2016). But, what is the effect of the domain of the corpus used to find the related sentences, is the question we focus on in our data selection design.

Our aim is to study the improvements achieved by using the sentences from different genre/domain of corpora. However, to be able to extract sizeable amount of biomedical sentences, the corpora should not be very unrelated, for example, the Europarl corpus (Koehn, 2005) which is composed of Parliament proceedings would not be a good choice[1]. Our intent was to do a comparative study of quality of extracted sentences from varied but yet not too far off domain corpora. Thus, for mining related sentences from general domain corpora we used Books[2], News Commentary[3] and WikiPedia[4] corpus obtained from Open Parallel Corpus (OPUS) (Tiedemann, 2012).

French WikiPedia[5] (FrWikipediaMono) was also used which was available as monolingual corpus and was translated to English.

Corpus	Corpus Size	Retrieved Sentences	Unique Sentences
Books	127085	1235684	42827
News Commentary	209479	1244026	72011
WikiPedia	818302	1236092	105880
FrWikiPediaMono	8766978	938834	162743

Table 1: Number of sentences retrieved for each corpus for top-2 using French side of Medline tiltles as queries.

Our data selection strategy is graphically presented in figure 1. We followed the data selection approach based on IR as proposed by (Abdul-Rauf et al., 2016). The choice of corpus to use as queries was a critical one: queries should have maximum biomedical terminologies to enable targeting and choosing domain specific sentences from the general domain corpora. We chose Medline titles as queries hypothesising on the fact that the title essentially contains the specific domain terminology. We used English side of Medline titles as queries when retrieving similar sentences

[1] It must have some biomedical sentences from parliamentary debates on health issues, but the amount will be very little.

3 Corpora

In this section, we present details of corpora used to train our systems, pre-processing and training parameters. We used the in-domain corpora provided by the organizers along with our mined in-domain sentences from the general domain corpora. The in-domain corpora included were:

- Ufal medical corpus, where a subset of medical corpora were extracted including CESTA, ECDC, EMEA, Subtitles and patTR medical corpus. (Yepes et al., 2017)
- Scielo corpus that included scientific biodomain articles. (Neves et al., 2016)
- EDP dataset containing documents from EDP database for scientific publications. (Névéol et al., 2018)
- Medline abstracts and titles from publications.(Bawden et al., 2019)

Books, News Commentary, WikiPedia and FrWikipediaMono corpora were used as the outdomain corpora to perform in data selective training experiments by extracting relevant in-domain sentences as explained in section 2. Development set included EDP, Scielo and Khresmoi (Dušek et al., 2017). Medline test corpora provided by WMT18 (Neves et al., 2018) and WMT19 (Bawden et al., 2019) were used as test sets.

3.1 Pre-processing

Our pre-processing pipeline includes data cleaning, punctuation normalization, tokenization, truecasing and subword segmentation.

Data cleaning was done to remove noisy data. Some of the provided corpora, including EDP, Scielo and Subtitles, were not completely aligned so we used Microsoft's bilingual sentence aligner[6] (Moore, 2002) for their complete alignment. Empty lines, hyperlinks, parenthesis, white spaces if present at the beginning of sentences were removed. Sentences having more than 120 tokens were dropped using Moses cleaning scripts (Koehn et al., 2007), punctuation and normalization was also applied. Table 2 shows our corpus sizes in terms of number of sentences (after cleaning).

For our French to English systems, we tokenized the corpora using Moses tokenizer[7]. Byte Pair Encoding (BPE) sub word units with a vocabulary of 32K units were computed on true cased data using `subword-nmt` (Sennrich et al., 2015) . BertTokenizer[8] was only used for our submitted English to French system.

Table 3: BLEU scores for (BERT-fused NMT) French to English Models trained with selective data training from out-of-domain corpus

3.2 Training and Parameters

We used Fairseq (Ott et al., 2019), an open-source toolkit for training simple transformer (Vaswani et al., 2017) model and Bert-nmt[9] for training BERT-fused NMT systems. Our experiments can be grouped in three categories depending upon the corpora used during training and their training approach. I) Models trained using all the in-domain corpora provided by WMT. II) Models trained on all the in-domain WMT corpora with addition of in-domain corpus retrieved from out-of-domain corpora using IR. III) Models fine tuned on Medline abstracts and titles (since test corpus is from Medline), from few models built in second category. We used transformer base (Vaswani et al., 2017) architecture provided by fairseq as `transformer_iwslt_de_en`. Adam optimizer and a batch size of 4K words was used in all the experiments. Training was done till complete convergence, models were checked for improvements on test data, and training was stopped if no further improvement in BLEU scores is calculated after 2-3 successive checkpoints. For BERT-fused NMT models same training parameters were used as for NMT models except that multilingual bert base was incorporated during training following the approach of (Zhu et al., 2020)

4 Experiments and Results

In this section we report the details of the experiments we performed for our participation in the WMT20 Biomedical task. We performed several different experiments to investigate the performance of NMT with different training approaches. Several different models were trained for French to English translation direction and one model was trained for English to French translation direction. The experiments were conducted as an extension of our last year's submission (Hira et al., 2019) with two different objectives. First, to investigate the performance of BERT-fused NMT over state-of-the art transformer model and the other to explore the effect of out-of-domain corpus used for selective data training. We evaluated our models on Medline 18 and Medline 19 test sets, scores were calculated using sacrebleu (Post, 2018).

4.1 Corpus Selection for Selective Data training

The significant gains in performance due to selective data training, as achieved in our WMT19 participation moved us to explore further to catego-

ID	Approach	Training sets	Test sets	
French to English			**Medline 18**	**Medline 19**
M1	Transformer	WMT	33.2	36.3
M2	BERT-fused transformer (cased)	WMT	29.5	32.6
M3	BERT-fused transformer (uncased)	WMT	29.6	34.7
R1	BERT-fused transformer (SD)	WMT + all IR2	31.8	37.2
R2	R1 fine tuned	WMT + all IR2	35.1	**38.4**
R3	BERT-fused transformer (SD)	WMT + all IR3	29.7	34.0
R4	R3 fine tuned	WMT + all IR3	**47.5**	36.8
English to French				
M4	Transformer	WMT + Books + WikiPedia	**32.5**	**35.8**

Table 4: BLEU scores for BERT-fused NMT with IR incorporated French to English models.

rize which out-of-domain corpus is a better choice. We extended out-of-domain corpora to four different resources for selective data training. Alongwith News Commentary, which was also used in WMT19 participation, we extended the list with WikiPedia corpus, Books corpus and back translated FrWikipediaMono corpus. These were used to build four different sets of models from $S1$ to $S4$ as listed in Table 3. Adding the IR retrieved data has unanimously helped improve the scores to almost 3 BLEU points on both test sets.

These models were trained using WMT20 in-domain corpora with addition of selective `top-1`, `top-2` and `top-3` retrieved IR sentences. $S1$ represents models built using additional News commentary IR corpus. Best scores were obtained on `top-2` yielding 33.1 and 36.8 BLEU points on Medline 18 and Medline 19 test sets. $S2$ consists of models trained on additional Books IR corpus and best scores were again achieved on `top-2` giving 32.9 and 37.0 points on Medline 18 and Medline 19 test sets. $S3$ comprises of models trained using additional WikiPedia IR corpus that reveal change in trend by giving best points 33.1 on `top-1` for Medline 18 and 37.2 on `top-2` for Medline 19 test sets. Similarly, systems represented by $S4$ show the effect of adding back translated FrWikipediaMono IR corpus in training set, that followed the trend of $S1$ and $S2$ giving best points 32.5 and 36.9 on `top-2` for Medline 18 and Medline 19 respectively. We can safely conclude that `top-2` IR retrieved sentences give us the best score. As for the effect of domain/type of the corpus used for IR, we don't see any significant advantage of any corpus over the other. For example, News Commentary and Books are very different corpora, but still sentences from both the corpora yield more or less the same improvement. Same is the case with WikiPedia, whether parallel or monolingual. This is an expected outcome as the IR process retrieves the sentences most relevant to the query sentence (Medline titles in our case).

4.2 BERT-fused NMT

To target our second objective, investigation of BERT-fused NMT performance over transformer model, we trained three models using in-domain data provided by WMT20 Bio-medical translation task; $M1$, $M2$ and $M3$. And four models, $R1$ to $R4$, using additional IR data, for French to English translation direction. Whereas 1 model ($M4$) for English to French translation direction, as shown in table 4. $M1$ was trained with simple transformer architecture without BERT fusion and it scored 33.2 and 36.3 BLEU points on Medline 18 and Medline 19 test sets respectively. $M2$ was trained under BERT-fused NMT setting with cased multilingual BERT base fused in transformer architecture. This model yielded 29.5 BLEU score on Medline 18 and 32.6 BLEU score on Medline 19 test set. Unexpectedly $M2$, despite being trained in BERT-fused NMT setting, didn't show improvements in BLEU points over simple transformer model ($M1$). One reason of this unexpected decrease in the BLEU scores of $M2$ over $M1$ could be the use of BERT trained on general domain. It seems that BERT

trained on much huge general domain corpus has suppressed the learned parameters from in-domain training corpus. $M3$ was trained as similar to $M2$ but with uncased BERT, to explore the difference in the performance of cased and uncased BERT model, and it showed little improvement than $M2$ on Medline 18 test data with a difference of only 0.1 BLEU points whereas an increase of 2.1 BLEU points on Medline 19 test set, as listed in Table 4. Based on this result, we selected uncased BERT model for our further experiments.

Further, we tried to evaluate the performance of selective data training in BERT-fused NMT setting, and trained four models for this investigation as shown in Table 4. $R1$ was trained over in-domain WMT20 corpus concatenated with `top-2` queried all IR data, since these proved to be most beneficial as shown by the results from section 4.1. $R1$ scored 31.8 and 37.2 BLEU points on Medline 18 and Medline 19 test sets respectively. Comparing $R1$ with $M2$ depicts that BERT-fused NMT also benefits from data selective training approach, as the results show considerable increase in BLEU points, increasing 2.3 and 2.5 BLEU scores on Medline 18 and Medline 19 respectively by adding only 0.3M (308426 sentences) IR data. Though the addition of IR data for training $R1$ improved scores compared to $M2$ but did not outperform $M1$ which initiated the need to verify our assumption that general domain BERT is suppressing the learned parameters from in-domain training data. So, for verification we fine tuned $R1$ on Medline abstracts and Medline titles data to train a new system $R2$. $R2$ showed improvements in scores as fine tuned on in-domain corpus (Medline abstracts and titles). It gave highest BLEU score points of 38.4 for medline 19 test set and also producing 35.1 BLEU points on Medline 18. This verify that our assumption about the unexpected results of BERT-fused NMT model was correct. Another model $R3$ was built to test the effect of queried IR data. $R3$ was trained over in-domain WMT20 corpus concatenated with `top-3` queried all IR data. It yielded 29.7 and 34.0 BLEU scores on Medline 18 and Medline 19 respectively. $R3$ is then fine tuned on Medline abstracts and Medline titles data to train a new system $R4$. $R4$ scored highest BLEU points of 47.5 for Medline 18 and gave 36.8 BLEU points for Medline 19 test set.

For English to French translation direction, we trained transformer model with hugging face BERT tokenizer instead of BERT-fused NMT ($M4$). The model was trained with transformer architecture on in-domain data and selective data from Books and WikiPedia corpus. This model ranked third in official results provided by WMT20 and scored 32.5 and 35.8 BLEU points on Medline 18 and Medline 19 test sets respectively.

5 Related Work

Numerous challenges arise when dealing with biomedical data used for translation due to limited size of corpus and unstructured alignments. Various approaches have been adopted by researchers in WMT biomedical translation. (Khan et al., 2018) submitted a NMT system that combined in-domain data set and used transfer learning approach to train the model along with ensemble learning. (Huck et al., 2018) trained by using transformer architecture using biomedical and news domain and employed cascaded word segmentation along with BPE. (Tubay and Costa-jussà, 2018) emphasize on using multi-source approach like Romance languages with in-domain data by implementing transformer architecture using OpenNMT in PyTorch. (Carrino et al., 2019) created terminology list for biomedical words using BabelNet API, inserted the information at a token level and trained NMT system using transformer model (Vaswani et al., 2017). (Hira et al., 2019) used selective learning for building additional corpus from out-of-domain data and incorporated transfer learning approach by using recurrent encoder decoder NN model for training of in-domain biomedical data.(Peng et al., 2019) trained their Transformer model on in-domain and out-of-domain data for six translations using transfer learning methods. The model used attention mechanism along with RELU activation function yielding better results for in-domain biomedical data. (Saunders et al., 2019) used transfer learning using Bayesian Interpolation for multi-domain data for ensemble weighting. (Soares and Krallinger, 2019) participated in WMT19 with four translation directions by creating concatenating corpora from UMLS, out-of-domain and in-domain data and trained the systems using Transformer model.

6 Conclusion

In this paper, we present our submission for WMT20 Biomedical tasks. Our model trained for English to French language direction ranked third in official scores provided by WMT20. We trained

different models to investigate the performance of BERT-fused NMT over transformer model and to explore the effect of selective data training in BERT-fused NMT for French to English language direction. Results show decline in performance of BERT-fused NMT models over transformer architecture as general domain BERT suppressed the learned parameters from in-domain training corpus. BERT-fused models yielded better results when fine tuned on in-domain corpus and trained with IR data.

Abstract

This paper describes Huawei's submissions to the WMT20 biomedical translation shared task. Apart from experimenting with fine-tuning on domain-specific bitexts, we explore effects of in-domain dictionaries on enhancing cross-domain neural machine translation performance. We utilize a transfer learning strategy through pre-trained machine translation models and extensive scope of engineering endeavors. Four of our ten submissions achieve state-of-the-art performance according to the official automatic evaluation results, namely translation directions on English⇔French, English→German and English→Italian.

1 Introduction

Neural machine translation (NMT) models built upon the Transformer architecture (Vaswani et al., 2017) start to dominate the leader board of WMT biomedical shared tasks in recent years (Bawden et al., 2019). In-domain data (parallel and monolingual corpora) have been widely used in finetuning general domain NMT models. Despite ongoing improvements on the translation quality observed from recent biomedical shared tasks, domain adaptation remains an open problem. The in-domain data is hard to obtain and, as a consequence, greatly limits the cross-domain translation capability an NMT model can offer. Domain terminologies, on the other hand, are regarded as critical resources to improve the quality of machine translation by mitigating effects of scarce in-domain bitexts (Bawden et al., 2019). However, few research works leverage domain-specific terminologies (or dictionaries) in training cross-domain NMT systems.

In this paper, we present the system architecture and research approaches underpinning Huawei's submissions to the WMT20 biomedical translation task. We implement two NMT systems to maximize the performances of the shared task. The system I is an in-house NMT system built upon the transformer-big architecture (Vaswani et al., 2017) and trained using general domain data. We explore means to enhance cross-domain coverage of an NMT model by finetuning the NMT model with in-domain bitexts. We also investigate the effects of domain dictionaries in this domain adaptation process. Reusing pre-trained models has been regarded as an efficient way of transfer learning. Pre-trained NMT models (Ng et al., 2019) are adopted in the system II to this end.

All NMT systems are evaluated against the test set released in the WMT19 biomedical shared task. We submitted translated results for a total of ten language directions between English (EN) and other five languages including French (FR), German (DE), Italian (IT), Russian (RU) and Chinese (ZH). Four of the submissions achieve the best BLEU scores according to the official automatic evaluation results. Substantial increases in BLEU scores are recorded in translation directions of DE→EN (+3.9 BLEU), ZH→EN (+3.5 BLEU), and EN→DE (+2.8 BLEU) compared to our submissions last year (Peng et al., 2019). The improvements on EN⇔DE can be ascribed to strong pre-trained NMT baseline models and a series of optimization techniques, for example, in-domain data augmentation and a reranking method with strong language models. High-quality in-domain data and large-scale back-translation contribute to the improvements of the ZH→EN model.

2 The Data

Table 1 captures the number of sentences pairs used in this shared task. The system I is trained using in-house general domain data (OOD) and finetuned on the in-domain data (IND) provided by

Proceedings of the 5th Conference on Machine Translation (WMT), pages 857–861
Online, November 19–20, 2020.

Directions		Train				Dev.	Test	Vocab.
		OOD	IND	IND-Dict.	IND-Aug.

	RU→EN	-	54K	-	-	300	-	32K(EN)/31K(RU)

Table 1: Data used for training and finetuning systems I and II. Note that "IND-Dict." refers to the in-domain dictionary. "IND-Aug." is the augmented data derived from processing IND data. For the system I, "IND-Aug." is created from back-translating monolingual data. For the system II, "IND-Aug." is the pre-processed IND data in combination with the data selected from some OOD data based on the similarity to the Medline data. M is for "million," and K stands for "thousand".

WMT20.[1] The in-domain data consist of bitexts from EMEA (Tiedemann, 2012), UFAL,[2] Pubmed, and Medline.[3] The data is processed by methods in the next section. The test data for the system I are from the WMT19 shared task.

The data used for finetuning the system II are different from those for the system I. The system II only focuses on Medline as we discovered it is the most effective IND data for this shared task. The development (dev.) set for the system II is the OK-aligned test data from the WMT19 biomedical shared task.

A batch of monolingual Medline data in English dated before July 2018 has been extracted to provide a basis for data augmentation and noisy channel model reranking (Ng et al., 2019). It produces the augmented IND data for the ZH→EN translation direction via back-translation ("IND-Aug." in Table 1). Due to time and resource constraints, we could not fully explore this monolingual Medline data in other translation directions.

3 The Approaches

The proposed systems are finetuned and enhanced using the following methods. All models are trained on Tesla V100 GPUs. Systems I and II use batch sizes of 6,144 and 8,000 tokens respectively in the finetuning process.

3.1 In-domain Dictionary

Bilingual dictionaries have been studied in the machine translation community for various purposes. The lexicons are used to enhance the translation quality for rare and unknown words in the parallel corpus (Zhang and Zong, 2016). Research works in domain adaptation for NMT showed that incorporating domain-specific dictionaries is a viable solution (Hu et al., 2019; Thompson et al., 2019; Peng et al., 2020). Inspired by these studies, we apply domain-specific dictionaries derived from SNOMED-CT, [4] which is a collection of multilingual clinical terminology, to finetune general domain NMT models to boost cross-domain coverage. The dictionaries are treated as bitexts attached to the end of training data.

3.2 Reranking

Apart from adopting a data-driven approach mentioned above, we also apply a transfer learning approach by reusing the publicly available pre-trained NMT models provided at fairseq (Ott et al., 2019). [5] After finetuning the selected pre-trained NMT models on the in-domain data, we apply a noisy channel model reranking method (Ng et al., 2019). The weights λ in Equation 1 are learned with a

Table 2: BLEU scores of the system I on all related submissions. The baseline models are finetuned (ft) in various configurations, including mixed finetuning on in-house OOD data (aka BS), IND bitexts, "IND-Dict." and the augmented IND data ("IND-Aug."). Note that the WMT20 best official score for ZH→EN excludes those results currently under investigation.

random search for the best performing candidate on the validation data.

$$\lambda_1 logP(y|x) + \lambda_2 logP(y) + \lambda_3 logP(x|y) \quad (1)$$

Due to time constraints, we did not implement the reranking approach on the system I.

3.3 Data Processing

A data processing pipeline is applied to enhance the quality of training data:

- Data cleaning is implemented to filter out noisy data. An important step is to handle misalignment in the parallel corpus. An alignment model trained by fast-align (Dyer et al., 2013) [6] is applied to this end (Lu et al., 2018). In addition, we remove bitexts with a source and target sentence length ratio exceeding a certain threshold (i.e., 2.5). A language detection tool [7] is used to filter out bitexts with abnormal language patterns, i.e., sentences with undesirable *langid*. Other noisy data, such as those with HTML tags and extra spaces, are removed.
- Scripts from Moses (Koehn et al., 2007) are used to perform punctuation normalization and tokenization. SentencePiece (Kudo and Richardson, 2018) segments words into subwords.
- We extract "in-domain" data which are close to Medline from general domain data by using TFIDF-based similarities. Similar data augmentation approaches can be identified in Wang et al. (2017) and Peng et al. (2020).
- Post-processing is performed after decoding to detokenize subwords and remove undesirable spaces between special characters and numbers, i.e., converting "23 - 25" into "23-25".

4 Experimental Results

The systems are trained with OOD data and finetuned using IND data to produce the submitted results. We benchmarked the submissions using WMT19 test data. The BLEU scores are calculated using the MTEVAL script from Moses (Koehn et al., 2007). Results are shown in Table 2 and Table 4. The final two rows demonstrate the scores of our submissions on this year's test sets and the best official records released by the organizers.

4.1 English ⇔ French

The system I is our in-house system equipped with an extensive data processing pipeline to handle noisy data, i.e., the application of sentence alignment and language detection tools. Our EN→FR and FR→EN submissions achieve the best official results in the WMT20 shared task. IND bitexts and "IND-Dict." have contributed to up to 2.7 BLEU in enhancing the baseline performance. We presume the improvement is due to the enhanced domain coverage the IND data brought forth. Note that even with much larger OOD bitexts than last year, the system produces similar benchmark scores. It appears an over-representation of OOD data is not helpful in cross-domain NMT. An analysis of domain coverage is performed to investigate the effect of IND information on cross-domain translation. We count the number of unique terms (1-2 grams)

Data	EN→FR		FR→EN	
	Unigrams	Bigrams	Unigrams	Bigrams
OOD	2,763	5,752	2,989	6,317
OOD + IND + IND-Dict.	2,773 (+10)	5,827 (+75)	2,997 (+8)	6,372 (+55)

Table 3: Domain coverage analysis for data used to train English⇔French.

System II	EN→DE	DE→EN	EN→RU	RU→EN
baseline	34.12	37.39	-	-
+ ft All Medline	35.58 (+1.46)	39.06 (+1.67)	-	-
+ ft Pre-proc. Medline	36.90 (+1.32)	40.98 (+1.92)	27.30	33.38
+ ft IND-Aug.	37.13 (+0.23)	41.79 (+0.81)	-	-
+ reranking	38.17 (+1.04)	42.74 (+0.95)	-	-
WMT19 Submission	35.39	38.84	-	-
WMT20 Submission	**36.89**	**41.46**	**34.64**	**43.03**
WMT20 Best Official	**36.89**	**41.65**	**39.36**	**43.31**

Table 4: BLEU scores of system II on English ⇔ German. "Pre-proc." stands for "pre-processed." Note that "IND-Aug." contains the pre-processed Medline data and the data derived from OOD via TFIDF selection. Numbers in the brackets depict the incremental increase from the baseline models.

at the intersection of a data source (i.e., the OOD training data) and the test data. Table 3 indicates that the increase of BLEU may be associated with a level of domain coverage enhancement. An increasing number of distinctive IND terms is recorded.

4.2 English ⇔ German

We perform ablation tests on pre-trained NMT models (the system II) in English ⇔ German under various conditions. As shown in Table 4, an EN→DE model finetuned on a preprocessed version of Medline outperforms that trained on the full version of Medline by 1.32 BLEU, indicating the effectiveness of the data preprocessing method. The EN→DE model finetuned on the "IND-Aug." data adds 0.23 to the BLEU score. The performance of the model can be boosted by 1.04 BLEU using the reranking method. Both EN→DE and DE→EN models outperform our last year's submissions significantly by 2.78 and 3.90 BLEU, respectively.

4.3 Other Translation Directions

The submissions for other translation directions are illustrated in Table 2 and Table 3. Note that we did not perform the experiments on the same level as those for English⇔German due to time constraints. It is observed that finetuning on IND data has contributed to improving the performance of baseline models in EN→IT, IT→EN, and ZH→EN directions. The result for EN→ZH is inconclusive, most likely due to potential issues during training.

5 Conclusion

This paper depicts Huawei's submissions to the WMT20 biomedical shared task. For all ten translation directions, we have explored the effects of using IND bitexts and dictionaries on enhancing the performances of cross-domain NMT. We have demonstrated the benefits of the transfer learning strategy of reusing pre-trained NMT models. Four of our ten submissions achieve the best records according to the released WMT20 official results.

Acknowledgments

We would like to show our gratitude to colleagues from Huawei Noah's Ark Lab, AARC, Huawei Translation Service Center, and HTRDC AIE for their support during this work.

Addressing Exposure Bias With Document Minimum Risk Training: Cambridge at the WMT20 Biomedical Translation Task

Danielle Saunders and **Bill Byrne**

Department of Engineering, University of Cambridge, UK

Abstract

The 2020 WMT Biomedical translation task evaluated Medline abstract translations. This is a small-domain translation task, meaning limited relevant training data with very distinct style and vocabulary. Models trained on such data are susceptible to exposure bias effects, particularly when training sentence pairs are imperfect translations of each other. This can result in poor behaviour during inference if the model learns to neglect the source sentence.

The UNICAM entry addresses this problem during fine-tuning using a robust variant on Minimum Risk Training. We contrast this approach with data-filtering to remove 'problem' training examples. Under MRT fine-tuning we obtain good results for both directions of English-German and English-Spanish biomedical translation. In particular we achieve the best English-to-Spanish translation result and second-best Spanish-to-English result, despite using only single models with no ensembling.

1 Introduction

Neural Machine Translation (NMT) in the biomedical domain presents challenges in addition to general domain translation. Text often contains specialist vocabulary and follows specific stylistic conventions. For this task fine-tuning generic pre-trained models on smaller amounts of biomedical-specific data can lead to strong performance, as we found in our 2019 biomedical submission (Saunders et al., 2019). For our WMT 2020 submission we start with strong single models from that 2019 submission and fine-tune them exclusively on the small Medline abstracts training sets (Bawden et al., 2019). This allows fast training on very relevant training data, since the test set is also made up of Medline abstracts.

However, fine-tuning on relevant but small corpora has pitfalls. The small number of training examples exacerbates the effect of any noisy or poorly aligned sentence pairs. We treat this as a form of exposure bias, in that model overconfidence in training data results in poor translation hypotheses at test time.

Our contributions in this system paper are:

- A discussion of exposure bias in the form of imperfect training data, focusing on the biomedical domain.
- An exploration of straightforward ways to mitigate exposure bias via data preparation and training objective.
- A discussion of our 2020 Biomedical task results for single models fine-tuned on small, domain-specific data sets.

1.1 Exposure bias in the biomedical domain

Exposure bias for an autoregressive sequence decoder refers to a discrepancy between decoder conditioning during training and inference (Bengio et al., 2015; Ranzato et al., 2016). During training the decoder generates a hypothesis for the t^{th} output token $\hat{y}_t$ conditioned on $y_{1:t-1}$, the gold target sequence prefix. During inference, the gold target y is unavailable, and $\hat{y}_t$ is conditioned instead on the hypothesis prefix $\hat{y}_{1:t-1}$.

Previous work has interpreted the risk of exposure bias primarily in terms of the model over-relying on correct gold target translations, resulting in error propagation when mistakes are made during inference. We take a different view, focusing on mistakes in the training data which harm the model through teacher-forcing exposure and cause it to make related mistakes during inference.

We identify a specific feature of the Medline abstract training data which caused noticeable translation errors. The data contains instances in which either the source or target sentence contains the

Table 1: Two sentence from the English-German 2020 test set with hypothesis translations from various models, demonstrating the effects of exposure bias from training on imperfectly aligned training sentences. The first MLE example output is completely unrelated to the source sentence, but the second MLE translation is more misleading.

correct translation of the other sentence, but adds information that is not found in translation. For example, the following sentence appears in the English side of en-de Medline abstract training data:

[The effects of Omega-3 fatty acids in clinical medicine]. Effects of Omega-3 fatty acids (n-3 FA) in particular on the development of cardiovascular disease (CVD) are of major interest.

Its corresponding German sentence is

Der Nutzen von Omega-3-Fettsäuren (n-3-FS) in der Medizin, hauptsächlich in der Prävention kardio- und zerebrovaskulärer Erkrankungen, wird aktuell intensiv diskutiert. (Translated: 'The uses of Omega-3 fatty acids in medicine, especially in prevention of cardiovascular and cerebrovascular diseases, are currently heavily discussed.')

Some of the English sentence is present in the German translation, but the square-bracketed article title is not. In this example it might be possible to remove only the segment in square brackets, but in other examples there is even less overlap, while source and target sentences may still be related and therefore challenging to filter. For example, the following English and German sentences also correspond with still less overlap:

[Conflict of interest with industry–a survey of nurses in the field of wound care in Germany , Australia and Switzerland]. Background.

Hintergrund: Pflegende werden zunehmend von der Industrie umworben. (Translated: 'Background: Nurses are being increasingly courted by industry.')

These examples are quite frequent in Medline abstract data, especially in the form of titles. It is common to insert the English title of a non-English article into its translation, marked with square brackets (Patrias and Wendling, 2007). The marked title is not present in the original article. Consequently models trained on English source sentences with titles can behave erratically when given sentences with square-bracketed titles at test time: an exposure bias effect.

One possible approach to this problem is aggressively filtering sentences which may be poorly aligned. However, with such a small training set, this risks losing valuable examples of domain-specific source and target language. We hypothesise that such filtering is not the only way to reduce the effects during inference. Instead, we propose an approach in terms of the parameter fine-tuning scheme with Minimum Risk Training (MRT). Wang and Sennrich (2020) have recently shown MRT as effective for combating exposure bias in the context of domain shift – test sentences which are very different from the training data. We propose that MRT is also more robust against exposure to misaligned training data.

The examples in Table 1 show the different behaviour of MLE and MRT in such cases. In the first example, the MLE hypothesis is unrelated to the source sentence, while the MRT output is relevant. In the second example, the MLE output is more plausible and therefore misleading, as it still misses the first clause which the MRT hypothesis covers. Both MLE and MRT hypotheses are phrased like opening sentences rather than titles, and both feature the untranslated phrase 'Additional Case Study': while MRT may be more robust, it is not immune to exposure bias.

We note that title translations may not exist in the human reference. In these cases failure

to translate the title will not negatively impact BLEU. However, we argue a biomedical translation model should be able to translate such sentences if required. It is also important to note that title translations are not the only case of inexact training pairs, but are simply easily identifiable.

1.2 Document MRT

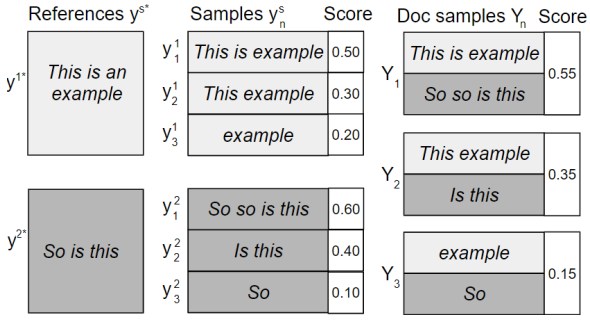

Figure 1: Two MRT schemes with an $S = 2$ sentence minibatch and $N = 3$ samples / sentence. In standard MRT (middle) each sample has a score, e.g. sBLEU. For doc-MRT (right) samples are sorted into minibatch-level 'documents', each with a combined score, e.g. document BLEU. Doc-MRT scores are less sensitive to individual samples, increasing robustness.

Minimum Risk Training (MRT) aims to minimize the expected cost between N sampled target sequences $\boldsymbol{y_n^{(s)}}$ and the corresponding gold reference sequence $\boldsymbol{y}^{(s)*}$ for the S sentence pairs in each minibatch. For translation MRT is usually applied using a sentence-level BLEU (sBLEU) score corresponding to cost function $1 - \text{sBLEU}$, and sentence samples are generated by autoregressive sampling with temperature τ during training (Shen et al., 2016). Hyperparameter α controls sharpness of the distribution over samples. While MRT permits training from scratch, in practice it is exclusively used to fine-tune models.

Doc-MRT is a recently proposed MRT variant which changes sentence cost function to a document cost function, $D(.)$ (Saunders et al., 2020). D measures costs between minibatch-level 'documents' Y^* and Y_n. Y^* is formed of all S reference sentences in the minibatch, and Y_n is one of N sample 'documents' each formed of one sample from each sentence pair $(\boldsymbol{x}^{(s)}, \boldsymbol{y}^{(s)*})$. This permits MRT under document-level scores like BLEU, instead of sBLEU. The n^{th} sample for the s^{th} sentence in the minibatch-level document, $\boldsymbol{y}_n^{(s)}$, contributes the following term to the overall gradient:

$$\frac{\alpha}{N} \sum_{Y:\boldsymbol{y}^{(s)}=\boldsymbol{y}_n^{(s)}} D(Y, Y^*) \nabla_\theta \log P(\boldsymbol{y}_n^{(s)} | \boldsymbol{x}^{(s)}; \theta)$$

In other words the gradient of each sample is weighted by the aggregated document-level scores for documents in which the sample appears.

Figure 1 gives a toy example of doc-MRT scoring samples in context. Document-level metrics aggregate scores across sentence samples, meaning a minibatch with some good samples and some poor samples will not have extreme score variation. Doc-MRT is therefore less sensitive than standard MRT to variation in individual samples.

Doc-MRT has been shown to give better performance than standard MRT for small datasets with a risk of over-fitting, as well as improved robustness to small N. More discussion of these results and a derivation of the document-level loss function can be found in Saunders et al. (2020). Since we are attempting fine-tuning on small datasets and since N is a limiting factor for MRT on memory-intensive large models, the biomedical task is an appropriate application for doc-MRT.

1.3 Related work

Fine-tuning general models on domain-specific datasets has become common in NMT. Simple transfer learning on new data can adapt a general model to in-domain data (Luong and Manning, 2015). Mixed fine-tuning where some original data is combined with the new data avoids reduced performance on the original data-set (Chu et al., 2017). We are only interested in performance on one domain, so use simple transfer learning.

For this task, we specifically fine-tune on a relatively small dataset. Adaptation to very small, carefully-chosen domains has been explored for speaker-personalized translation (Michel and Neubig, 2018) , and to reduce gender bias effects (Saunders and Byrne, 2020) while maintaining general domain performance. We wish to adapt to a very specific domain without need to maintain good general domain performance, but must avoid overfitting. Related approaches include fine-tuning a separate model for each test sentence (Li et al., 2018; Farajian et al., 2017) or test document (Xu et al., 2019; Kothur et al., 2018). We choose to train a single model for all test sentences in a language pair, but improve the robustness of that model to overfitting and exposure bias using MRT.

Table 2: Biomedical training and validation data used in the evaluation task. For both language pairs identical data was used in both directions. Bolded numbers are totals after filtering

MRT has been widely applied to NMT in recent years (Shen et al., 2016; Neubig, 2016; Edunov et al., 2018). In particular, Wang and Sennrich (2020) recently highlighted the efficacy of MRT for reducing the effects of exposure bias.

2 Experimental setup

2.1 Data

We report on two language pairs: English-Spanish (en-es) and English-German (en-de). Table 2 lists the data used to train our biomedical domain evaluation systems. For each language pair we use the same training data in both directions, and preprocess all data with Moses tokenization, punctuation normalization and truecasing. We use a 32K-merge joint source-target BPE vocabulary (Sennrich et al., 2016) learned on the pre-training data.

All of our submitted approaches involve fine-tuning pre-trained models. We initialise fine-tuning with the strong biomedical domain models that formed our 'run 1' submission for the WMT19 biomedical translation task. Details of data preparation and training for these models are discussed in Saunders et al. (2019).

We fine-tune these models on Medline abstracts data, validating on test sets from the 2019 Biomedical task. For these we concatenate the src-trg and trg-src 2019 test sets for each language pair, and select only the 'OK' aligned sentences as annotated by the organizers.

Before fine-tuning we carry out detected language filtering on the Medline abstracts fine-tuning data using the Python LangDetect package[6]. We find LangDetect has a tendency to incorrectly label short sentences or those with rare vocabulary (very common in Medline) as a random language. For each language pair we therefore filter out only sentences where LangDetect identifies the source sentence as belonging to the target language, and vice versa.

We then use a series of simple heuristics to further filter the parallel datasets, removing duplicate sentence pairs, those with source/target length ratio of $<$ 1:3.5 or $>$ 3.5:1, and sentences with $>$ 120 tokens. For the more aggressively-filtered 'no-title' experiments we additionally remove all lines containing multiple tokens in square brackets, which in medical writing are used to denote the English translation of a non-English article's title (Patrias and Wendling, 2007). This leaves 27.3K sentence pairs for en-de and 64.8K for en-es: about 96% of the filtered data in both cases.

2.2 Model hyperparameters and training

We use the Tensor2Tensor implementation of the Transformer model with the `transformer_big` setup for all NMT models (Vaswani et al., 2018). We use the same effective batch size of 4k tokens for both MLE and doc-MRT. Because of model size constraints and the need to sample multiple targets for doc-MRT, we achieve the 4k effective batch size by accumulating gradients (Saunders et al., 2018) over every 4 batches of 1k tokens for MLE and every 16 batches of 256 tokens for doc-MRT.

For doc-MRT we use sampling temperature $\tau = 0.3$, smoothing parameter $\alpha = 0.6$ and $N = 8$ samples per sentence, which gave the best results for our doc-MRT experiments in Saunders et al. (2020).

		de2en	en2de	es2en	en2es
1	Baseline	38.8	30.6	48.5	46.6
2	MLE fine-tuning from 1	40.9	32.5	48.5	46.0
3	Checkpoint averaging 2 (en-de) / 1 (en-es)	41.1	32.2	48.5	47.1
4	MRT from 1	40.0	31.1	**49.0**	47.4
5	MRT from 2 (en-de only)	**41.3**	32.9	-	-
6	Checkpoint averaging 5 (en-de) / 4 (en-es)	**41.3**	**33.0**	48.9	**47.7**

Table 3: Validation BLEU developing models used in English-German and English-Spanish language pair submissions. Scores for single checkpoints unless indicated. MLE fine-tuning did not improve over the en-es baselines, so we do not use these models to initialise MRT.

	de2en	en2de	es2en	en2es
MLE from baseline	41.1	32.2	-	-
MLE from baseline, no-title	41.4	31.8	-	-
MRT from: MLE (en-de) / baseline (en-es)	41.3	**33.0**	48.9	**47.7**
MRT no-title from: MLE no-title (en-de) / baseline (en-es)	**41.9**	32.6	**49.0**	47.2

Table 4: Validation BLEU developing models used in English-German and English-Spanish language pair submissions. Scores for averaged checkpoints. MLE fine-tuning with either dataset did not improve over the en-es baselines.

For each approach we fine-tune on a single GPU, saving checkpoints every 1K updates, until fine-tuning validation set BLEU fails to improve for 3 consecutive checkpoints. Generally this took about 5K updates. We then perform checkpoint averaging (Junczys-Dowmunt et al., 2016) over the final 3 checkpoints to obtain the final model.

2.3 Inference

For the 2020 submissions, we additionally split any test lines containing multiple sentences before inference using the Python NLTK package[7], translate the split sentences separately, then remerged. We found this gave noticeable improvements in quality for the few sentences it applied to. In all cases we decode with beam size 4 using SGNMT (Stahlberg et al., 2017). Test scores are as provided by the organizers for "OK" sentences using Moses tokenization and the multi-eval tool. Validation scores are for case-insensitive, detokenized text obtained using SacreBLEU[8] (Post, 2018).

2.4 Results

We first assess the impact of small-domain adaptation to the full title-included Medline training set. Results in Table 3 show that small-domain MLE can lead to over-fitting and reduced performance (en-es) but also significant gains (en-de). Further fine-tuning with doc-MRT improved performance relative to the best MLE model for all translation directions by up to 0.8 BLEU when comparing with or without checkpoint averaging. While checkpoint averaging slightly decreased validation set performance for en2de MLE, we use it in all cases since it reduces sensitivity to randomness in training (Popel and Bojar, 2018).

In Table 4 we explore the impact of fine-tuning only on aggressively filtered 'no-title' data. This does noticeably improve performance for de2en, with a very small improvement for es2en. Since the added information in 'title' sentences is on the English side, this suggests that target training sentence quality impacts both MLE and MRT performance. However, removing these sentences entirely results in a noticeable performance decrease for the en2de and en2es models, demonstrating that they can be valuable training examples.

We submitted three runs to the WMT20 biomedical task for each language pair. For en-de run 1 was the baseline model fine-tuned on MLE with all data, while for en-es we submitted the checkpoint averaged baseline as MLE fine-tuning did not improve dev set performance. Run 2 was the run 1 model fine-tuned with doc-MRT on no-title data. Run 3 was the run 1 model fine-tuned with doc-MRT on all Medline abstract data. Table 5 gives scores for these submitted models.

Our best runs achieve the best and second-best results among all systems for en2es and es2en respectively as reported by the organizers. For en-de our test scores are further behind other systems, perhaps indicating that the baseline system could have been stronger before fine-grained adaptation.

MRT (no-title data)	**41.9**	39.6	32.6	32.8	**49.0**	46.4	47.2	**46.7**
MRT (all data)	41.3	**39.8**	**33.0**	**33.2**	48.9	**46.6**	47.7	46.6

Table 5: Validation and test BLEU for models used in English-German and English-Spanish language pair submissions. Test results are for "OK sentences" as scored by the organizers.

This is also indicated by the strong improvement of these models under simple MLE.

We submitted the MRT model on no-title data instead of the MLE on no-title data because MLE optimization did not improve over the baseline for en-es or en-es, with or without title lines, whereas MRT fine-tuning did. We also wanted to further examine whether MRT was robust enough to benefit from 'noisy' data like the title lines, or whether cleaner no-title training data was more useful. In fact both forms of doc-MRT performed similarly on the test data, except in the case of en2de, where 'no-title' MRT scored 0.4 BLEU worse – further confirmation that source sentences with more information than the gold target can benefit MRT. We note that a MRT run was the best run or tied best run in all cases.

For the test runs, we additionally experimented with simply removing square bracket tokens from source sentences, since these could act as 'triggering' tokens for title sentences. This did seem to improve translations for the sentences it applied to, but is clearly not applicable to all forms of exposure bias, since it requires knowledge of all behaviours that could trigger exposure bias. MRT does not require such knowledge, but still reduces the effects of exposure bias.

3 Conclusions

Our WMT20 Biomedical submission investigates improvements on the English-German and English-Spanish language pairs under a single strong model. In particular, we focus on the behaviour of models trained on sentences with some predictable irregularities. We find that aggressively filtering target sentences can help overall performance, but that aggressively filtering source sentence tends to hurt performance. We also find that Minimum Risk Training can benefit from imperfectly aligned training examples while reducing the effects of exposure bias.

Abstract

This paper describes the machine translation systems developed by the University of Sheffield (UoS) team for the biomedical translation shared task of WMT20. Our system is based on a Transformer model with TensorFlow Model Garden toolkit. We participated in ten translation directions for the English/Spanish, English/Portuguese, English/Russian, English/Italian, and English/French language pairs. To create our training data, we concatenated several parallel corpora, both from in-domain and out-of-domain sources.

1 Introduction

In this paper, we present the system developed by the University of Sheffield for the Biomedical Translation shared task in the Fifth Conference on Machine Translation (WMT20), which consists in translating scientific texts from the biological and health domain.

Our participation in this task considered the English/Portuguese, English/Spanish, English/Russian, English/Italian, and English/French language pairs with translations in both directions. For that matter, we developed a machine translation (MT) system based on neural machine translation (NMT), using Google's TensorFlow Model Garden. [1]

2 Related Works

Previous participation in biomedical translation tasks include the works of Costa-Jussà et al. (2016) which employed Moses Statistic Machine Translation (SMT) to perform automatic translation integrated with a neural character-based recurrent neural network for model re-ranking and bilingual word embeddings for out of vocabulary (OOV) resolution. Given the 1000-best list of SMT translations, the RNN performs a re-scoring and selects the translation with the highest score. The OOV resolution module infers the word in the target language based on the bilingual word embedding trained on large monolingual corpora. Their reported results show that both approaches can improve BLEU scores, with the best results given by the combination of OOV resolution and RNN re-ranking. Similarly, Ive et al. (2016) also used the n-best output from Moses as input to a re-ranking model, which is based on a neural network that can handle vocabularies of arbitrary size.

More recently, Tubay and Costa-Jussà (2018) employed multi-source language translation using romance languages to translate from Spanish, French, and Portuguese to English. They used data from SciELO and Medline abstracts to train a Transformer model with individual languages to English and also with all languages concatenated to English.

In the last two WMT biomedical translation challenges (WMT18 and WMT19) (Neves et al., 2018; Bawden et al., 2019), the submissions that achieved the best BLEU scores for the ES/EN and PT/EN, in both directions (Soares and Becker, 2018; Tubay and Costa-Jussà, 2018; Carrino et al., 2019; Saunders et al., 2019; Soares and Krallinger, 2019), used the Transformer architecture with enhancements such as handling of terminology during tokenization (Carrino et al., 2019), multi-domain inference (Saunders et al., 2019) and exploitation of additional linguistic resources (Soares and Becker, 2018; Soares and Krallinger, 2019).

3 Resources

In this section, we describe the language resources used to train both models.

Online, November 19–20, 2020.

3.1 Corpora

We used both in-domain and general domain corpora to train our systems. For general domain data, we used the ParaPat patent corpus (Soares et al., 2020), which is available for several languages, included the ones we explored in our systems. As for in-domain data, we included several different corpora:

- The corpus of full-text scientific articles from SciELO (Soares et al., 2018a), which includes articles from several scientific domains in the desired language pairs, but predominantly from biomedical and health areas.
- A subset of the UFAL medical corpus[2], containing the Medical Web Crawl data for the English/Spanish language pair.
- The EMEA corpus (Tiedemann, 2012), consisting of documents from the European Medicines Agency.
- A corpus of theses and dissertations abstracts (BDTD) (Soares et al., 2018b) from CAPES, a Brazilian governmental agency responsible for overseeing post-graduate courses. This corpus contains data only for the English/Portuguese language pair.
- A corpus from Virtual Health Library[3] (BVS), containing also parallel sentences for the language pairs explored in our systems.
- A corpus from SciELO (Neves et al., 2016), containing also parallel sentences from abstracts in English/Portuguese, English/Spanish, and English/French.

A new crawl of MEDLINE using the Ebot provided by the National Library of Medicine.[4]

Table 1 depicts the original number of parallel segments according to each corpora source. In Section 4.1, we detail the pre-processing steps performed on the data to comply with the task evaluation.

[2] https://ufal.mff.cuni.cz/ufal_medical_corpus

[3] http://bvsalud.org/

[4] https://www.ncbi.nlm.nih.gov/Class/PowerTools/eutils/ebot/ebot.cgi

4 Experimental Settings

In this section, we detail the pre-processing steps employed as well as the architecture of the Transformer.

4.1 Pre-processing

As detailed in the description of the biomedical translation task, the evaluation is based on texts extracted from MEDLINE. Since two of our corpora, the one comprised of full-text articles from SciELO and the new crawl from PubMed, may contain a considerable overlap with MEDLINE data, we decided to employ a filtering step in order to avoid including such data.

The first step in our filter was to download the parallel data from PubMed articles in Russian, French, and Italian. For that matter, we used the Ebot utility[5] provided by NLM using the queries *ITA[la]*, *FRE[la]*, and *RUS[la]*, retrieving all results available. Once downloaded, we performed sentence alignment using LF-Aligner[6]. To perform the filtering, we decided to use simple case insensitive string matching with *grep* supplying the option *-xvf* and the test set in English.

4.2 NMT System

As for the NMT system, we employed the official Google's implementation of the Transformer architecture (Vaswani et al., 2017) to train ten MT systems for the five language pairs. Tokenization was performed using the WordPiece unsupervised tokenizer with a vocabulary size of 32,000 on the initial training data, with a shared vocabulary between source and target.

For systems where the target language was English, back-translation was used with a number of sentences equals to the initial training system where English was the source. For the Spanish/English language pair, the system used to produce the artificial parallel sentences was the one developed by Soares and Krallinger (2019), while for the other language pairs we used the same systems trained by our team.

The parameters of our network for all language pairs excluding English/Portuguese are as follows. Encoder and Decoder: Transformer; Word vector size: 512; Layers for encoder and decoder:

[5] https://www.ncbi.nlm.nih.gov/Class/PowerTools/eutils/ebot/ebot.cgi

[6] https://sourceforge.net/projects/aligner/

Corpus	Sentences				
	EN/ES	EN/PT	EN/FR	EN/RU	EN/IT
ParaPat	-	-	-	3.28M	-
UFAL	286,779	-	1.6M	-	-
Abstract SciELO	767,069	669,629	-	-	-
Full-text SciELO	425,631	2.86M	-	-	-
EMEA	1.01M	1.08M	609,852	-	1.08M
CAPES-BDTD	-	950,252	-	-	-
BVS	-	931,946	10,812	-	-
MEDLINE (titles and abstracts)	-	-	582,007	11,271	1,298
Total	2.48M	6.49M	2.25M	3.28M	1.08M

Table 1: Original size of individual corpora used in our experiments

6; Attention heads: 16; RNN size: 512; Hidden transformer feed-forward: 2048; Batch size: 8196. For the English/Portuguese language pair, due to the large training set, we employed a bigger network as follows. Word vector size: 1024; Layers for encoder and decoder: 6; Attention heads: 16; RNN size: 1024; Hidden transformer feed-forward: 4096; Batch size: 8192.

To train our systems, we used 5 Tensor Processing Units (TPUs) v3, with a number of 250,000 steps (for all systems with exception of Russian, which was trained with fewer steps). The models with the best perplexity value were chosen as final models.

For the English/Russian language pair, incremental training was performed, since the size of the in-domain dataset was reduced. For such, we first trained our system in the out-of-domain data from patents for 100,000 steps. We then proceeded with additional training for 25,000 steps with in-domain data.

5 Results

We now detail the results achieved by our Transformer systems on the official test data used in the shared task regarding automatic evaluation. Table 2 shows the BLEU scores (Papineni et al., 2002) for our systems for the 10 language pairs we participated. For the Spanish and Portuguese language pairs we achieve high competitive results. For ES/EN, the best system (NLE) achieved BLEU of 0.5075, while the second best achieved BLEU of 0.4662 (TRAMECAT), very close to our result of 0.4624. For the opposite direction, EN/ES, the best system (UCAM) achieved 0.4662, the second best (Elhuyar_NLP) 0.4498, while our system scored 0.4493.

Language Pair	**BLEU**
EN/PT	0.4744
PT/EN	0.5334
EN/ES	0.4493
ES/EN	0.4624
EN/FR	0.3049
FR/EN	0.3514
EN/RU	0.2573
RU/EN	0.2936
EN/IT	0.2073
IT/EN	0.2276

Table 2: Official BLEU scores for the language pairs we submitted systems. These scores are evaluated on the "OK" aligned sentences.

For the Portuguese language, in both directions we achieved the best scores, with an EN/PT BLEU of 0.4744 and PT/EN of 0.5334. The second team in both languages (UNICAMP_DL) achieved scores of 0.4095 and 0.4988, respectively.

As for the Russian, French, and Italian languages, our scores were not as competitive as the best systems, with the exception of FR/EN, which we stood as 3 out of 5 teams. After carefully checking our training data, we found encoding issues with the different gathered data for those languages, especially with the encoding and tokenization of words containing apostrophes in French and Italian, as well as the Cyrillic Kha.

6 Conclusions

We presented the University of Sheffield (UoS) machine translation system for the biomedical translation shared task in WMT20. For our submission, we trained ten Transformers NMT systems, employing different corpora for each language pair. In addition, for systems with English as target language, back-translation was used, and for the Russian language, incremental training from Patent abstracts was used.

For model building, we included several corpora from biomedical and health domain, and from out-of-domain data that we considered to have similar textual structure, such as books and patents. Prior training, we also pre-processed our corpora to ensure that we did not include any sentence from the released test set, which could produce biased models.

Regarding future work, we are planning on optimizing our systems by performing pre-selection of out-of-domain data, aiming at selecting only the most similar sentences to the in-domain data. In addition, we plan to explore the potential use of domain-specific decoding, as proposed in Saunders et al. (2019).

Ixamed's submission description for WMT20 Biomedical shared task: benefits and limitations of using terminologies for domain adaptation

Xabier Soto, Olatz Perez-de-Viñaspre, Gorka Labaka, Maite Oronoz

{xabier.soto, olatz.perezdevinaspre, gorka.labaka, maite.oronoz }@ehu.eus

Abstract

In this paper we describe the systems developed at Ixa for our participation in WMT20 Biomedical shared task in three language pairs, en-eu, en-es and es-en. When defining our approach, we have put the focus on making an efficient use of corpora recently compiled for training Machine Translation (MT) systems to translate Covid-19 related text, as well as reusing previously compiled corpora and developed systems for biomedical or clinical domain. Regarding the techniques used, we base on the findings from our previous works for translating clinical texts into Basque, making use of clinical terminology for adapting the MT systems to the clinical domain. However, after manually inspecting some of the outputs generated by our systems, for most of the submissions we end up using the system trained only with the basic corpus, since the systems including the clinical terminologies generated outputs shorter in length than the corresponding references. Thus, we present simple baselines for translating abstracts between English and Spanish (en/es); while for translating abstracts and terms from English into Basque (en-eu), we concatenate the best en-es system for each kind of text with our es-eu system. We present automatic evaluation results in terms of BLEU scores, and analyse the effect of including clinical terminology on the average sentence length of the generated outputs. Following the recent recommendations for a responsible use of GPUs for NLP research, we include an estimation of the generated CO_2 emissions, based on the power consumed for training the MT systems.

1 Introduction

The WMT20 Biomedical shared task calls for developing systems for translating biomedical abstracts and terminologies between several languages. In our case, we participate in the task of translating biomedical terms and abstracts from English into Basque (en-eu), as well as translating biomedical abstracts between English and Spanish (en-es and es-en). For translating the test data from English into Basque, we concatenate our best en-es system with our es-eu system, both for translating abstracts and terminologies.

2 Related work

For translating biomedical texts from English into Catalan, Costa-jussá et al. (2018) use a pivoting or cascade approach, translating the texts first from English into Spanish (en-es), and then from Spanish into Catalan (es-ca). This technique is useful when there are more bilingual in-domain sentences for each of the language pairs (en/es and es/ca) than for the desired source and target languages (en/ca). Since there are low resources for en/eu biomedical domain, but we have access to many resources for en/es and es/eu in the biomedical or clinical domain, we follow the same approach for translating the test sets from English into Basque (en-eu).

Since most of the available in-domain corpus is monolingual, we also make use of traditional back-translation and forward translation techniques (Sennrich et al., 2016).

In our previous work for translating clinical texts between Basque and Spanish, we showed that including clinical terminologies directly into the training corpus was useful for domain adaptation when no bilingual in-domain sentences were available (Soto et al., 2019a). As clinical terminologies, we refer to the automatic translation into Basque of SNOMED CT (IHTSDO, 2014), which is considered the most comprehensive, multilingual clinical health care terminology collection in the world. In this work, we extend the number of clinical terminologies as part of the ongoing translation of SNOMED CT into Basque (Perez-de-Viñaspre,

Proceedings of the 5th Conference on Machine Translation (WMT), pages 875–880

2017), and include the provided ICD-10 resources plus other smaller terminology collections recently created for translating Covid-19 related texts.

3 Resources

For training our baseline en/es systems, we make use of the Medline corpus provided by the organisers of the WMT20 Biomedical shared task, as well as the recently compiled TAUS Corona Crisis Corpus.[1]

For backtranslation (es-en) and forward translation (en-es), we use the English corpus prepared by Sketch Engine[2], based on the Covid-19 related corpus compiled for a recent Kaggle competition (Wang et al., 2020).

As a final step, we include several clinical terminologies: 1) the ICD-10 (en-eu) corpus provided by the organisers of the WMT20 Biomedical shared task, adding the corresponding Spanish counterparts; 2) terms obtained from the automatic translation into Basque of SNOMED CT (Perez-de-Viñaspre, 2017), including terms up to 11 tokens; 3) a recent SNOMED CT interim release of Covid-19 related terms[3], manually translated into Basque by a translator of the Basque public health service (Osakidetza); and 4) a collection of Covid-19 related terms recently compiled by Elhuyar[4], including all the terms published until June 18[5].

For training our es-eu system, we use the aforementioned terminologies together with an out-of-domain corpus formed mainly by news (Etchegoyhen et al., 2016), previously applying a language identification tool[6] to exclude sentences where most of the terms are named entities like locations or person names. Doing this, a bigger part of the vocabulary can be used to translate biomedical or clinical terms. Furthermore, as in-domain corpus we use clinical notes in Spanish coming from the hospital of Galdakao-Usansolo for forward translation and copying (Currey et al., 2017). This corpus was compiled between 2008 and 2012.[7]

For the evaluation of en/es systems, we use Khresmoi;[8] while for es-eu we use templates of clinical notes in Basque written in the Donostia hospital (Joanes Etxeberri Saria V. Edizioa, 2014), together with their manual translations into Spanish made by a bilingual doctor.

Table 1 presents the description and statistics of our corpora.

	Description	Sentences
en/es	Medline (WMT Biomedical)	388,068
	TAUS Corona Crisis Corpus	902,133
	Sketch Engine Covid-19 (en)	4,671,609
	ICD-10 (WMT Biomedical)	27,696
	SNOMED CT corpus	385,800
	SNOMED CT Covid-19 corpus	84
	Elhuyar Covid-19 corpus	113
	Khresmoi (dev set)	500
	Khresmoi (test set)	1,000
es-eu	out-of-domain	3,703,757
	in-domain (es)	2,023,811
	ICD-10 (WMT Biomedical)	27,696
	SNOMED CT corpus	896,898
	SNOMED CT Covid-19 corpus	84
	Elhuyar Covid-19 corpus	126
	Donostia hospital (dev set)	1,038
	Donostia hospital (test set)	1,038

Table 1: Description and statistics of the used corpora.

4 Systems

For en/es we develop 3 systems: 1) using only the bilingual in-domain corpus (Medline + TAUS Corona Crisis Corpus), 2) including the Sketch Engine Covid-19 (en) corpus for backtranslation (es-en) or forward translation (en-es), and 3) adding all the clinical terminologies from ICD-10, SNOMED CT and Elhuyar.

For es-eu we train a unique system using the out-of-domain corpus and the clinical terminologies, as well as the in-domain (es) corpus for forward translation and copying.

For training the backtranslation (en-es) and forward translation (es-en) systems, we used the bilingual in-domain corpus (Medline + TAUS Corona Crisis Corpus); while for es-eu we used the out-of-domain corpus and a reduced set of SNOMED CT terminologies, as used in Soto et al. (2019b).

[5] when the English term was missing, if there was no doubt about how to translate it, the first author manually translated it; while if there wasn't a clear translation into English or the term was more related to socioeconomics than biomedical domain, it wasn't included in the en/es corpus.

[6] https://github.com/saffsd/langid.py

[7] Due to privacy requirements, this corpus is not publicly available. Prior to use, it was de-identified by reordering sentences, and only authors who had previously signed a non-disclosure commitment had access to it.

[8] https://lindat.mff.cuni.cz/repository/xmlui/handle/11234/1-2122

All the systems are Transformer (Vaswani et al., 2017) models trained with OpenNMT (Klein et al., 2017), using the recommended hyperparameters.[9] When necessary, we halved the batch-size so that it could fit in 2 GPUs, and accordingly doubled the value for gradient accumulation.

We applied joint BPE-dropout (Provilkov et al., 2020), with 32,000 merge operations for en/es and 90,000 for es-eu.

5 Results

Table 2 shows the BLEU scores of our systems on the validation (dev) and test sets presented in Table 1, together with previously published (es-eu) results for comparison.

Lang.	System	dev	test
es-en	Baseline (Medline + TAUS)	56.57	52.55
	Baseline + backtranslation (bt)	**61.60**	**57.25**
	Baseline + bt + terminologies	60.95	56.89
en-es	Baseline (Medline + TAUS)	48.02	46.30
	Baseline + forward translation (ft)	**50.20**	**47.19**
	Baseline + ft + terminologies	49.92	47.15
es-eu	Soto et al. (2019a)	11.30	**12.04**
	Soto et al. (2019b)	**11.85**	11.24
	This work	6.21	5.15

Table 2: BLEU scores for systems developed for es-en, en-es and es-eu translation directions (Lang.).

As expected, backtranslation significantly improves the es-en results (around 5 BLEU points); while the gains obtained with forward translation (en-es) are smaller (around 2 BLEU points in the dev set and around 1 BLEU point in the test set). However, we observe a slight decrease on BLEU values when including the clinical terminologies on the training corpus for both es-en and en-es systems. For further analysing this, we calculate the average sentence length of the different evaluation corpora as translated by the different systems. Table 3 shows the average sentence length of the validation (dev) and test sets after being translated by each of the es-en and en-es systems. As a reference, the average sentence length of the original dev and test sets are 22.70 (es) / 21.06 (en) and 24.03 (es) / 21.91 (en).

We observe that, except for the dev set translated by the en-es systems, the lower sentence length is always obtained when using the system including the clinical terminologies. This is confirmed by a fast check of the outputs generated when translating

Lang.	System	dev	test
es-en	Baseline (Medline + TAUS)	20.54	22.02
	Baseline + backtranslation (bt)	20.56	21.73
	Baseline + bt + terminologies	20.40	21.56
en-es	Baseline (Medline + TAUS)	22.75	23.87
	Baseline + forward translation (ft)	22.93	23.84
	Baseline + ft + terminologies	22.99	23.76

Table 3: Average sentence length of the different evaluation corpora as translated by the systems developed for es-en and en-es translation directions (Lang.).

the official test sets provided by the organisers, where we see that the sentences translated by these systems usually end before having translated all of the terms that appear in the input. Overall, the sentence lengths of the generated translations are closer to the original sentence lengths when using the baseline systems; therefore, for en-es and es-en we submit as best systems the translations produced by the baseline systems, using only Medline and TAUS corpora.

Regarding es-eu, in Table 2 we can see a severe decrease on BLEU scores comparing to our previous works. For training the system in Soto et al. (2019a) we used the same out-of-domain corpus (without applying langid.py) and a reduced set of SNOMED CT terminologies (151,111 entries), both directly and inserted into artificial sentences; while in Soto et al. (2019b) we used this same corpus without the artificial sentences, which didn't prove to be useful. Nevertheless, after manually checking the outputs generated by these 3 systems, we observe that the system developed for this work performs generally better, so we submit the translations produced by this system.[10] As we use a cascade approach for en-eu, we use the en-es system including the terminologies for translating abstracts; and the baseline system for translating terminologies, as these were the best performing systems on a fast human evaluation. [11]

Once we have selected the best performing systems for each of the language pairs, since we are allowed to submit 3 runs, in the case of en/es, for each of the developed systems we submit an ensemble of the 3 models which obtained higher BLEU

[9] http://opennmt.net/OpenNMT-py/FAQ.html#how-do-i-use-the-transformer-model (Accessed on July 18, 2020.)

[10] It has to be noted that the evaluation corpus used for es-eu has strong limitations, since the original sentences are written for encouraging medicine students to write correctly; while the translations into Basque made by a doctor are overall shorter, use simplified grammar, often omit verbs and punctuation, and use many acronyms.

[11] Both for en/es and en-eu systems, the translations of the first 10 sentences of the official test sets were checked; and in case of tie, the next 10 sentences were also observed.

scores in the dev set during training; while for en-eu we alternate between single and ensemble systems for each of the en-es and es-eu systems. Specifically, we submit as best system an ensemble of the baseline en-es system and a single es-eu system for translating terminologies; while we use a single en-es system including the terminologies and an ensemble es-eu system for translating abstracts.

Table 4 shows the BLEU scores obtained on the official test sets for each of the language pairs and submitted runs for translating abstracts, as provided by the organisers. We present in italics the result of the expected best system for each language pair, and in bold the highest BLEU score, as in previous tables.

Lang.	System	BLEU
es-en	Baseline (Medline + TAUS)	*40.65*
	Baseline + backtranslation (bt)	**40.71**
	Baseline + bt + terminologies	39.96
en-es	Baseline (Medline + TAUS)	***41.71***
	Baseline + forward translation (ft)	38.36
	Baseline + ft + terminologies	38.58
en-eu	single (en-es) + ensemble (es-eu)	*8.15*
	ensemble (en-es) + single (es-eu)	7.82
	ensemble (en-es) + ensemble (es-eu)	**8.84**

Table 4: BLEU scores on the official test sets for translating abstracts in es-en, en-es and en-eu translation directions (Lang.).

Comparing to the submissions made by other teams, our systems submitted for en/es obtain the lowest BLEU scores among all the participants; while for en-eu our best run is the second among the best runs of each participant, only surpassed by the three runs submitted by Elhuyar.

Finally, Table 5 presents the accuracy and BLEU scores obtained by our systems when used for translating terminologies (en-eu), as provided by the organisers.

Lang.	System	Acc.	BLEU
en-eu	single (en-es) + ensemble (es-eu)	0.12	13.14
	ensemble (en-es) + single (es-eu)	*0.08*	*7.21*
	ensemble (en-es) + ensemble (es-eu)	**0.13**	**14.81**

Table 5: Accuracy (Acc.) and BLEU scores on the official test set for translating terminologies in en-eu translation direction (Lang.).

Surprisingly, the obtained automatic scores are much lower than the ones obtained by the rest of the participants (between 0.73 and 0.78 for accuracy, and approximately 71 to 74 BLEU scores). However, the generated translations look quite sensible, so we expect the human evaluation will shed some light about the performance of our systems.

6 Measured power consumption and estimated CO_2 emissions

Following the recommendations by Strubell et al. (2019), we report the power consumed by our GPUs when training the systems developed for this work, along with the estimated CO_2 emissions. For calculating the training time, we use the time shown in the first and last lines of the log file generated while training the systems, including also the initial time for preparing the data, so the presented values constitute an upper bound of the actually consumed power. Nonetheless, we have to point out that OpenNMT makes an efficient use of the power capabilities of the GPUs, so we can say that the numbers shown here are an accurate estimation. Table 6 shows the number of GPUs, training time, power consumption and estimated CO_2 emissions for each of the developed systems. All the GPUs used for this work are Nvidia Titan Xp models with 250W power. We present the values of the different systems in the same order as in Table 2, and estimate the CO_2 emissions by applying equations (1) and (2) in Strubell et al. (2019), considering only the power consumed by our GPUs. Overall, the CO_2 emissions generated by our GPUs are approximately 329.44 lbs.

Lang.	GPUs	Time (hh:mm)	Power (kWh)	CO_2e (lbs)
es-en	4	43:19	43.33	65.31
	2	46:30	23.26	35.06
	2	45:37	22.82	34.39
en-es	4	45:09	45.16	68.07
	2	47:24	23.70	35.73
	2	47:21	23.68	35.69
es-eu	2	73:14	36.62	55.20
TOTAL				**329.44**

Table 6: Number of GPUs, training time, power consumption and estimated CO_2 emissions for each of the developed systems (same order as in Table 2).

7 Conclusion and future work

In this work, we have presented a simple proposal using previously compiled corpora from the biomedical or clinical domain, as well as clinical terminology included directly to the training corpora. Apart from calculating BLEU scores, we have also calculated the average sentence length of the generated translations for en/es systems, and observed that the systems including terminologies

performed generally worse than the baseline systems.

As future work, we plan to incorporate these clinical terminologies in a more efficient way (Dinu et al., 2019; Wang et al., 2019). For improving both training and evaluation, we'll also use bilingual clinical domain corpora being compiled now in collaboration with the Basque public health service (Osakidetza). Furthermore, since we have observed that some of the translations generated by the es-eu systems remain in Spanish, we'll study techniques to leverage in-domain monolingual data in Basque like the one provided by the organisers from Wikipedia.

Finally, we plan to keep reporting the consumed power and consequently generated CO_2 emissions, probably making use of recently developed automatic tools (Henderson et al., 2020)[12].

Tencent AI Lab Machine Translation Systems for the WMT20 Biomedical Translation Task

Xing Wang, Zhaopeng Tu, Longyue Wang, Shuming Shi
Tencent AI Lab, Shenzhen, China
{brightxwang,zptu,vinnylywang,shumingshi}@tencent.com

Abstract

This paper describes the Tencent AI Lab submission of the WMT2020 shared task on biomedical translation in four language directions: German⇒English, English⇒German, Chinese⇒English and English⇒Chinese. We implement our system with model ensemble technique on different transformer architectures (DEEP, HYBRID, BIG, LARGE Transformers). To enlarge the in-domain bilingual corpus, we use back-translation of monolingual in-domain data in the English language as additional in-domain training data. Our systems in German⇒English and English⇒German are ranked 1st and 3rd respectively according to the official evaluation results in terms of BLEU scores.[1]

1 Introduction

Neural machine translation (Bahdanau et al., 2015; Vaswani et al., 2017, NMT) has achieved great progress in recent years. However, as Koehn and Knowles (2017) pointed out, NMT systems suffer from poor translation performance in out-of-domain scenarios, which poses a great challenge for the biomedical translation task.

In this paper, we present our submission to the WMT20 shared task on biomedical translation task. We participated in two language directions: German-English and Chinese-English. To address the domain problem, on one hand, we adopt model ensemble technique (Liu et al., 2018) with different transformer architectures to build a more robust model. On the other hand, we enlarge the in-domain bilingual corpus with back-translation approach (Sennrich et al., 2016a).

Our contributions are as follows:

- We adopt the model ensemble technique and the back-translation approach to achieve the state-of-the-art performance on WMT19 biomedical translation task test sets.
- To promote further studies, we release some pre-trained models and the in-domain synthetic Chinese-English bilingual data for the community.

The rest of this paper is organized as follows. Section 2 presents our system with four different transformer architectures: DEEP, HYBRID, BIG, LARGE Transformers. Section 3 describes the training data used in our system, including bilingual data, monolingual data and synthetic bilingual data. Section 4 reports experimental results in two language directions. Finally, we conclude our work in Section 5.

2 System

In our systems, we adopt four different model architectures with TRANSFORMER (Vaswani et al., 2017):

- **DEEP** TRANSFORMER (Dou et al., 2018; Wang et al., 2019a; Dou et al., 2019) is the TRANSFORMER-BASE model with the 40-layer encoder.
- **HYBRID** TRANSFORMER (Hao et al., 2019b) is the TRANSFORMER-BASE model with 40-layer hybrid encoder. The 40-layer hybrid encoder stacks 35-layer self-attention-based encoder on top of 5-layer bi-directional ON-LSTM (Shen et al., 2019) encoder.
- **BIG** TRANSFORMER is the TRANSFORMER-BIG model as used by Vaswani et al. (2017).
- **LARGE** TRANSFORMER is similar to TRANSFORMER-BIG model except that it uses a 20-layer encoder.

[1]Details of our systems are introduced in https://github.com/hsing-wang/WMT2020_BioMedical

Proceedings of the 5th Conference on Machine Translation (WMT), pages 881–886
Online, November 19–20, 2020.

	DEEP	HYBRID	BIG	LARGE
Encoder Layer	40	40	6	20
Decoder Layer	6	6	6	6
Attention Heads	8	8	16	16
Embedding Size	512	512	1024	1024
FFN Size	2048	2048	4096	4096

Table 1: Hyper-parameters of different Transformer models used in our system.

The main differences between these models are presented in Table 1. Pre-Norm (Wang et al., 2019a) is adopted in above four models. All models are implemented on top of the open-source toolkit Fairseq[2]. Model ensemble is used through ensemble decoding with different model architectures.

3 Data

The data used to train our system consists of three parts: bilingual data, monolingual data and synthetic bilingual data.

3.1 Bilingual Data

In-domain bilingual data The in-domain bilingual data is provided by WMT20 biomedical translation shared task. For German-English, we choose Biomedical Translation[3] and UFAL Medical Corpus[4] to use as the in-domain training data. For Chinese-English out-of-domain (OOD) data, we adopt data selection (Axelrod et al., 2011; Liu et al., 2014) to select the in-house data (8.5M sentence pairs) as the in-domain training data.

General-domain bilingual data To alleviate the data scarce problem, we collect general-domain bilingual data from WMT20 news translation shared task[5]. For German-English, we use Europarl-v10[6], ParaCrawl-v5.1[7], News Commentary-v15[8] and Wiki Titles-v2[9]. For Chinese-English, we use CCMT Corpus[10], UN Parallel Corpus v1.0[11], News Commentary-v15[12].

3.2 Monolingual Data

As WMT20 biomedical translation shared task provides in-domain bilingual data in other language pairs, we gather in-domain monolingual data from bilingual data in other language pair. Specifically, we collect the English side of the bilingual sentence pairs from Biomedical Translation and UFAL Medical Corpus.

The statistics of the in-domain bilingual and monolingual data is listed in Table 2.

3.3 Synthetic Bilingual Data

To enlarge the in-domain bilingual corpus, we adopt back-translation method (Sennrich et al., 2016a) to generate synthetic bilingual sentence pairs. For Chinese-English, as we lack of sufficient in-domain bilingual data, we use an online translation system TranSmart[13] to translate the in-domain monolingual English back to Chinese. For German-English, we train a English-German LARGE model on the combination of in-domain and general-domain bilingual data, and use the model to generate synthetic bilingual data.

4 Experiment

We report experimental results in four language pairs: German-English (de/en), English-German (en/de), Chinese-English (zh/en) and English-Chinese (en/zh).

use Moses scripts[14] to preprocess[15] the data and filter the bilingual data with following heuristics rules:

- Filter out duplicate sentence pairs (Khayrallah and Koehn, 2018; Ott et al., 2018).
- Filter out sentence pairs with wrong language (Khayrallah and Koehn, 2018).
- Filter out sentences pairs containing more than 120 tokens or fewer than 3.
- Filter out sentence pairs with source/target length ratio exceeding 1.5 (Ott et al., 2018).

4.2 Evaluation

For German-English, we use the Khresmoi development data as the development set, and use the sentence pairs with the correct alignment in WMT19 biomedical translation task test set as our test set. For Chinese-English, we use the in-house bilingual test set (1,000 sentence pairs) and the sentence pairs with the correct alignment in WMT19 biomedical translation task test set as development set and test set, respectively.

Follow Bawden et al. (2019), we use multi-bleu.perl from Moses[16] to compute BLEU scores and report case-sensitive BLEU scores on development and test sets.

Data Pre-processing For each language pair, we perform byte-pair encoding[17] (BPE) (Sennrich et al., 2016b) processing on the combination of in-domain bilingual data and general-domain bilingual data, and set the number of BPE merge operations to 50,000 for source and target sides, respectively.

Model Training The learning rate is set to 0.0007. All models are trained for 600K steps on 8 Tesla V100 GPUs where each is allocated with a batch size of 8192 tokens.

4.3 German-English Results

For German-English task, we first train the models on the general-domain data. Then we combine the general-domain data and the in-domain data and train the models from scratch. Finally, we introduce the synthetic bilingual data to the combination data and use all data to train the models. The model

with best validation loss throughout the training process is selected as the final model for the testing. For model inference, the length penalty is set to 0.6 and the beam size is set to 4.

The German-English results are listed in Table 3. Our observations are:

- Due to the largest model capacity, LARGE model obtains the best translation performance among the four model variants.
- Ensemble decoding with different transformer architectures (ENSEMBLE in Table 3) achieves best translation performance.
- Leveraging in-domain bilingual data ("+In-domain") and synthetic bilingual data ("+BT In-domain") achieves significant translation improvement.

Data rejuvenation[18] (Jiao et al., 2020) is an approach which exploits the inactive training examples for neural machine translation on large-scale datasets. We adopt the data rejuvenation approach to German⇒English translation task. Experimental results are presented in Tale 7 and the data rejuvenation approach achieves significant improvement over the baseline LARGE model.

4.4 Chinese-English Results

For Chinese-English task, we gradually add the general-domain data, the synthetic bilingual data and OOD in-house data to the training data and train the models from scratch. Since the development set and test set have different data distribution, we save checkpoints every epoch and average the last 5 checkpoints rather than choose the model with best validation loss. For model inference, the length penalty is set to 2.0 and the beam size is set to 8.

Similar phenomena are observed in Chinese-English translation task. Table 4 shows Chinese-English translation results. Finally, our systems obtain 32.24 BLEU points and 33.23 BLEU points on the development and test sets, respectively.

4.5 Main Results

Main results are reported in Table 5. Our submissions (**T**encent AI Lab **M**achine **T**ranslation, TMT) with model ensemble technique achieve strong performances in WMT19 German⇔English and Chinese⇔English biomedical test sets.

5 Official Results

The official automatic evaluation results of our submissions for WMT 2020 are presented in Table 6. Our final systems rank the 1st and 3rd places on German-English and English–German, respectively, in terms of BLEU score.

6 Conclusion

In this paper, we present Tencent AI Lab machine translation systems for the WMT20 biomedical translation shared task and release the pre-trained models as well as the in-domain synthetic Chinese-English bilingual data for the research commu-

ParBLEU: Augmenting Metrics with Automatic Paraphrases for the WMT'20 Metrics Shared Task

Rachel Bawden[1] **Biao Zhang**[1] **Andre Tättar**[2] **Matt Post**[3]
[1]School of Informatics, University of Edinburgh, Scotland
[2]University of Tartu, Tartu, Estonia
[3]Johns Hopkins University, Baltimore, Maryland, USA

Abstract

We describe parBLEU, parCHRF++, and parESIM, which augment baseline metrics with automatically generated paraphrases produced by PRISM (Thompson and Post, 2020a), a multilingual neural machine translation system. We build on recent work studying how to improve BLEU by using diverse automatically paraphrased references (Bawden et al., 2020), extending experiments to the multilingual setting for the WMT2020 metrics shared task and for three base metrics. We compare their capacity to exploit up to 100 additional synthetic references. We find that gains are possible when using additional, automatically paraphrased references, although they are not systematic. However, segment-level correlations, particularly into English, are improved for all three metrics and even with higher numbers of paraphrased references.

1 Introduction

One of the major challenges faced when automatically evaluating machine translation (MT) outputs is that there are almost always multiple correct translations of a sentence, and an automatic metric should be able to reward them all. Some of the most widely used MT metrics, including BLEU (Papineni et al., 2002) and CHRF++ (Popović, 2015, 2017), rely on a surface-form comparison of MT outputs to a human-produced reference translation. Both metrics support the use of multiple references. However, even for metrics that support multiple references, human-produced references are expensive to produce and so are rarely available. To overcome this problem, metrics that do not rely on the surface form of reference translations have been developed. One example is ESIM (Chen et al., 2017; Mathur et al., 2019), which uses contextual embeddings with the aim of creating an abstract meaning representation of the reference, with the potential of covering all translations with the correct meaning.

We explore an alternative way of increasing the capacity of MT metrics to reward multiple valid translations: create additional references by automatically paraphrasing the original reference. There have been previous efforts to provide some sort of paraphrase support, mostly concentrating on synonyms (Banerjee and Lavie, 2005; Kauchak and Barzilay, 2006; Denkowski and Lavie, 2014). However, we base our work on a more recent attempt to improve BLEU using diverse automatic parahrasing with high quality MT-style *sentential* paraphrasing (Bawden et al., 2020).

We put this to the test in the WMT'20 metrics shared task by applying Bawden et al.'s (2020) approach to three different metrics: BLEU, CHRF++ and ESIM. We compare the different metrics' capacity to exploit automatically generated multiple references. We choose to use diverse paraphrases produced using PRISM (Thompson and Post, 2020a), since they are available in multiple languages, including most languages of the WMT shared task. We find that gains in correlation are possible, but this depends largely on the language direction and on whether the metric is system- or segment-level. The most positive gains are seen at the segment level, especially for into-English and even at higher numbers of additional paraphrases. This holds for all three metrics, despite ESIM relying on more abstract semantic representations.

2 Overview of Base Metrics

In an extension of (Bawden et al., 2020), we augment three base metrics with automatic paraphrasing. The metrics vary in the basic units of comparison between MT outputs and the reference. BLEU and CHRF++ compare surface representations, BLEU at the token level, whereas CHRF++ also takes into account character n-grams. ESIM is an embedding-based metric, which aims to cap-

Proceedings of the 5th Conference on Machine Translation (WMT), pages 887–894
Online, November 19–20, 2020.

ture the semantic relatedness of the sentences. A description of each base metric can be found below.

2.1 BLEU

BLEU (Papineni et al., 2002) is the dominant metric in MT. It is a modified form of n-gram precision, calculated by averaging token n-gram precisions (p_n, $n = 1..4$) and multiplying by a brevity penalty (BP) used to penalise overly short translations:

$$\text{BLEU} = \text{BP} \cdot \exp\left(\sum_{n=1}^{N} w_n \log p_n\right) \quad (1)$$

$$\text{BP} = \begin{cases} 1 & \text{if } c > r \\ e^{1-r/c} & \text{if } c \leq r \end{cases} \quad (2)$$

$$p_n = \frac{\sum_{h \in H} \sum_{\text{ngram} \in h} \#_{\text{clip}}\left(ngram\right)}{\sum_{h' \in H} \sum_{\text{ngram'} \in h'} \#\left(ngram'\right)}, \quad (3)$$

where c and r are the lengths of the hypothesis and reference sets respectively, H is the set of hypothesis translations, $\#\left(ngram\right)$ the number of times *ngram* appears in the hypothesis, and $\#_{\text{clip}}(ngram)$ is the same but clipped to the maximum number of times it appears in any one reference (if several references are available).

BLEU is typically used in its corpus-based variant, where a single score is produced for a test set. However, a segment-level variant also exists, where each sentence is scored individually. Smoothing is necessary in this segment-level variant to counteract the effect of 0 n-gram precision.

We use the sacreBLEU implementation[1] of BLEU (Post, 2018), with default tokenisation (and `-tok zh` tokenisation for Chinese) and exponential smoothing for the sentence-level variant.

2.2 CHRF++

CHRF++ (Popović, 2017),[2] like BLEU, is a surface-based metric, but which relies on overlap in character n-grams as well as token n-grams (hence its name 'character n-gram F-score'). This theoretically gives it an advantage over BLEU, since it is able to reward partial token matches thanks to its character-level component.

The original chrF (Popović, 2015) was calculated as follows using just character-level n-grams:

$$ngrF\beta = (1 + \beta^2)\frac{ngrP \cdot ngrR}{\beta^2 \cdot ngrP + ngrR},$$

where $ngrP$ and $ngrR$ respectively stand for the arithmetic average of n-gram precision and recall over character n-grams from 1 to N, where β gives more or less weight to precision than recall. CHRF++ expands on this original metric by also including token-level n-grams in this calculation with n from 1 to M. The best results were found with $N = 6$ and $M = 1$ or 2. We use the settings used in the WMT19 shared task: $N = 6$, $M = 1$ and $\beta = 3$. Like BLEU, CHRF++ has a specific corpus-level and sentence-level variant.

2.3 ESIM

ESIM (Chen et al., 2017; Mathur et al., 2019), is an embedding-based metric, which relies on neural models to handle inter-sentence semantic relatedness, going beyond surface-level matching (as in BLEU and CHRF++). ESIM was originally proposed to compare and match sentence pairs for natural language inference (Chen et al., 2017). Mathur et al. (2019) adapted it to evaluate MT performance by pairing the human reference and the MT output as ESIM input. Following (Mathur et al., 2019),[3] we treat the evaluation task as a regression task, and train ESIM models on segment-level human judgments. We train ESIM on the WMT18 metric data for WMT19 evaluation, and WMT18+WMT19 metric data for WMT20 evaluation. ESIM is a sentence-level metric. Scores are averaged to produce a single score for a given corpus.

3 Experiment Setup

Paraphrase generation We use the PRISM system to generate paraphrases. PRISM is a many-many multilingual NMT system covering 39 languages, including all of those of WMT 2019, except Gujarati. In their submission to the WMT 2020 Metrics task, Thompson and Post (2020c) retrained PRISM with five additional languages: Gujarati (for WMT'19), and Inuktitut, Khmer, Pashto, and Tamil (for WMT'20). This provided almost complete coverage of the WMT 2019 and 2020 languages. We use this same model.

By design, PRISM approaches paraphrasing as a zero-shot translation task. As a result, while good for scoring, it is not a particularly good generative model, in terms of being able to produce diverse outputs. Thompson and Post (2020b) have tried to address this, but their implementation does not

Figure 1: Two examples of automatic paraphrasing from fi–en WMT'20 (original references in bold).

produce n-best lists. We therefore produce n-best lists from the model using Fairseq's built-in diverse beam search tool. For every reference in the WMT19 and WMT20 news test sets, we generate a 100-best list (Vijayakumar et al., 2016).[4]

Figure 1 shows examples of paraphrases of two fi–en WMT'20 references. Note that the paraphrases are divere and generally of high quality. However, the later paraphrases may be noisier.

Integrating multiple references We augment each of the base metrics described in Section 2 to produce three new metrics: parBLEU, parCHRF++ and parESIM. Both BLEU and CHRF++ have inbuilt support for multiple references. For ESIM, we calculate the score for each reference separately and then average them to get the final score.

Metrics Task Setup Awaiting the gold judgments for WMT'20, we test and report the results of each method on the WMT19 metrics task.[5] We follow the metrics task setup (Ma et al., 2019) by calculating the correlation with manual direct assessments (DA) of MT quality (Graham et al., 2013). System-level scores are evaluated using Pearson's r and segment-level correlations using Kendall's τ on the DA assessments converted into relative rankings. Statistically significant improvements (over the single-reference base metric) are marked in bold (with $p \leq 0.05$). Significance is calculated using the Williams test (Williams, 1959) at the system level and bootstrap resampling at the segment level.

[4]We pass the following arguments: `fairseq-interactive ... --beam 100 --nbest 100 --diverse-beam-groups 10 --diverse-beam-strength 1`

[5]http://statmt.org/wmt19/results.html

4 Results

The results are reported in the following three sections for each paraphrase-augmented metric: parBLEU (Section 4.1), parCHRF++ (Section 4.2) and parESIM (Section 4.3). We report results for up to 100 additional paraphrased references, except for parESIM, where we report up to 50 additional references due to the length of time needed to calculate results. There are some general trends:

- There is often a difference between into- and from-English language directions, with more positive results seen into English. This could be due to the potential better quality of the English paraphrases.
- Results are better for into-English at the segment-level, where adding paraphrases tends to help even with more paraphrases.

4.1 parBLEU

Results for parBLEU are found in Table 1 (system-level) and Table 2 (segment-level).

(b) To-English language directions

Table 1: parBLEU system-level results.

System-level results are variable, with a notable difference between into-English and from-English language directions. For a couple of from-English languages, there are some slightly higher correlations but these are not significant, and some deteriorations can be seen when adding paraphrase for others. Adding paraphrased references is more successful for into-English languages. For four of the language directions, adding the maximum number of 100 paraphrases provides the greatest significant correlation gains, suggesting that even more gains could be achieved with more paraphrases. These gains are illustrated in Figure 2a.

(b) To-English language directions

Table 2: parBLEU segment-level results.

Segment-level results show variability according to the language direction too. The greatest gains are seen for the into-English directions, and the highest scores are achieved for the higher order numbers of paraphrases. Some gains are seen for most from-English directions, even with higher numbers of paraphrases. Interestingly, the language directions that see gains at the segment level are not correlated with those that see gains at the system level.

4.2 parCHRF++

System-level and segment-level results can be found in Table 3 and Table 4 respectively. The CHRF++ baseline (0 extra references) is higher than the BLEU baseline for into-English at the system-level and into all languages (except Chinese) at the segment-level.

(b) To-English language directions

Table 3: parCHRF++ system-level results.

At the system level, as with parBLEU, greater gains are seen for into-English than from-English language directions: all into-English language directions bar fi–en show increases. Moreover, most into-English language directions continue to see improvements with higher numbers of references. This trend can be seen in Figure 2b.

(b) To-English language directions

Table 4: parCHRF++ segment-level results.

At the segment level, extra references help all into-English directions, although this does depend on the number of references added for some language directions. From-English, some slight gains are seen but in most cases, adding extra references degrades results. At the segment level, the best results can be seen with just one additional reference.

4.3 parESIM

System-level and segment-level results can be found in Table 5 and Table 6 respectively. As an automatic metric that relies on comparing continuous representations (aiming to abstract away from surface forms), we would expect paraphrases to help ESIM less than the two other metrics, for which surface form variation is one of the major limitations.

At the system level, additional paraphrases does not seem to help for any of the language directions, and is even harmful (decreasing correlations as the number of paraphrases is increased). This could be due to the addition of noise in the results, which treats semantically divergent hypotheses as valid. Note however that the correlations start from a strong base—baseline ESIM has a much higher correlation than BLEU and CHRF++.

The segment-level results are more positive: paraphrasing significantly helps four from-English directions (into cs, de, ru and zh). It brings even more positive gains for the into-English language directions, where the best results are often achieved with the higher numbers of additional paraphrases.

4.4 Additional parBLEU comparisons

Following the shared task, we explored some alternative versions of parBLEU.

Replacing the original reference Concurrently to Bawden et al. (2020), Freitag et al. (2020) also review paraphrasing for BLEU, although they focus on human paraphrasing. They find that better correlations are achieved by replacing the original reference with a human paraphrased one, as original references often display translationese. We test this observation here, but using our automatic paraphrases. Results are shown in Table 7 (system level) and Table 8 (segment level).

(b) To-English language directions

Table 8: parBLEU segment-level results when using the original reference versus the first paraphrase.

We find that replacing the original reference with its first paraphrase results in higher correlations for the into-English language directions at the system

level (although the gain is only significant for three directions), and there do not seem to be gains at the segment level. In general, it harms both correlation types for the from-English language directions, probably due to the better quality of the English paraphrasing compared to that of the other languages. This appears to confirm Freitag et al.'s observation, as long as the quality of the paraphraser is good enough, which is our hypothesis concerning the into-English language directions.

Type of paraphraser We compare three different paraphrasers for the into-English language directions: (i) the 'sampled' diverse paraphrasing approach from (Bawden et al., 2020), (ii) the n-best PRISM paraphrases, and (iii) the n-best diverse PRISM paraphrases used elsewhere in this paper. The results are given in Table 9. Somewhat surprisingly, even though they are not designed to be diverse, the n-best paraphrases give good correlations, at least up to 20 paraphrases, which was the maximum number tested with the sampled paraphraser. The sampled paraphrases also often perform better than the diverse approach produced by the PRISM paraphraser. One reason for this could be that the sampled paraphraser is trained specifically as an English paraphraser, whereas the PRISM paraphraser is multilingual (therefore providing greater support for automatic evaluation).

Exclusion of outliers Mathur et al. (2020) suggested that system-level correlations computed with Pearson's are artificially inflated due to the presence of outliers, which are typically very poorly performing systems with low human scores. They propose a method based on *mean average deviation* (MAD) to exclude those outliers. We applied this method to the WMT19 system-level data to exclude systems, and then recomputed the system-level correlations.

The complete results are in Table 10. Comparing this to Table 7, we see an absolute drop in values, but little to nothing in the way of reversals between the BLEU (single-reference, zero-paraphrase) baseline and the paraphrase methods.

5 Conclusions and Future Work

The goal with any metric is to balance accuracy with ease-of-use. For our submission to the WMT20 metrics task, we extended our work investigating paraphrased English references (Bawden et al., 2020), by using a multilingual paraphraser.

(b) To-English language directions

Table 10: System-level results with parBLEU with outlier systems excluded. The *removed* row denotes how many systems were considered to be outliers

One component of ease-of-use, particularly for a metric, is to avoid highly language-specific parameter searches. Our work here used a single model and diversity parameter setting. It is possible that other approaches would yield more success: for example, varying the number of references based on reference length or complexity, or looking at other diverse generation techniques. However they are not guaranteed to work and raise questions about

the usefulness of extending surface-based metrics in the neural age. BLEU is appealing because of its simplicity and universality, but the emerging evidence (cf. Mathur et al. (2020)) suggest that the most promising approach for future work in MT evaluation is in model-based deep-learning approaches. What is encouraging and also somewhat surprising is that the embedding-based ESIM also seems to benefit from the addition of automatically paraphrased references at the segment level, especially into English.

Abstract

We present an extended study on using pretrained language models and YiSi-1 for machine translation evaluation. Although the recently proposed contextual embedding based metrics, YiSi-1, significantly outperform BLEU and other metrics in correlating with human judgment on translation quality, we have yet to understand the full strength of using pretrained language models for machine translation evaluation. In this paper, we study YiSi-1's correlation with human translation quality judgment by varying three major attributes (which architecture; which intermediate layer; whether it is monolingual or multilingual) of the pretrained language models. Results of the study show further improvements over YiSi-1 on the WMT 2019 Metrics shared task. We also describe the pretrained language model we trained for evaluating Inuktitut machine translation output.

1 Introduction

Recent research on large-scale evaluation of automatic machine translation (MT) evaluation metrics (Ma et al., 2018, 2019; Mathur et al., 2020) showed that the newly proposed contextual embedding based metrics, like YiSi-1, BERTscore (Zhang et al., 2020) and ESIM (Mathur et al., 2019), significantly outperform BLEU (Papineni et al., 2002) and other metrics in correlating with human judgment on translation quality. YiSi-1 and BERTscore use contextual embeddings extracted from the pretrained language model, Devlin et al. (2018), as-is without further fine-tuning or fitting to existing labeled data predictions. Although fine-tuning the pretrained language models for specific downstream tasks show improvements in many cases, using the pretrained language models without fine-tuning makes the MT evaluation metrics more portable to languages without labeled data and the resulted metric scores are comparable to each other over time across systems. Thus, instead of spending efforts into fine-tuning the pretrained language models for MT evaluation, we focus on finding the most optimal way (which architecture; which intermediate layer; whether it is a monolingual or multilingual model) to utilize them as-is.

Zhang et al. (2020) investigated into a few aspects (architecture and layer) of the use of contextual embeddings in text generation evaluation. They evaluated several model architectures of different sizes, such as BERT (Devlin et al., 2018), RoBERTa (Liu et al., 2019), XLNet (Yang et al., 2019) and XLM (Lample and Conneau, 2019). As more pretrained language models that cover more languages are released since then, we extend the study on YiSi-1 to include more pretrained language models and also compare the effect of using monolingual pretrained models versus multilingual pretrained models.

In this paper, we experiment on different settings of YiSi-1 in the WMT 2019 metrics shared task, integrating it with different transformer-based (Vaswani et al., 2017) contextual language models in both monolingual or multilingual, such as BERT (Devlin et al., 2018), ALBERT (Lan et al., 2020), BART (Lewis et al., 2019), RoBERTa (Liu et al., 2019), XLM-RoBERTa (Conneau et al., 2020) and XLNET (Yang et al., 2019), using different intermediate layers. We show that YiSi-1's correlation with human judgment on translation quality is improved by using the results of this study.

2 YiSi

YiSi (Lo, 2019) is a unified semantic MT quality evaluation and estimation metric for languages with different levels of available resources. YiSi-1 measures the similarity between a machine

Proceedings of the 5th Conference on Machine Translation (WMT), pages 895–902

translation and human references by aggregating weighted distributional (lexical) semantic similarities, and optionally incorporating shallow semantic structures. YiSi-0 is the degenerate version of YiSi-1 that is ready-to-deploy to any languages by using longest common character substring, instead of cosine similarity of contextual embeddings, to measure lexical similarity.

YiSi-2 is the bilingual, reference-less version, which uses bilingual word embeddings to evaluate cross-lingual lexical semantic similarity between the input and MT output, and optionally incorporating shallow semantic structures. Improvements in YiSi-2 for WMT 2020 metrics shared task is detailed in (Lo and Larkin, 2020).

2.1 Pretrained Language Models

YiSi-1 relies on a language representation to evaluate the lexical semantic similarity between the reference translation and the MT output. In WMT 2019 metrics shared task, it used pretrained BERT (Devlin et al., 2018) for this purpose.

BERT captures the sentence context in the embeddings, such that the embedding of the same subword unit in different sentences would be different from each other and be better represented in the embedding space. Monolingual BERT pretrained model for English and Chinese and multilingual BERT pretrained that covers the 104 largest languages in Wikipedia were public released in 2019.

2.1.1 Monolingual models

Monolingual BERT in other languages After the success of using monolingual BERT models for downstream NLP tasks in Chinese and English, a number of monolingual BERT models in other languages have been publicly released, such as German (Chan et al., 2019), Finnish (Virtanen et al., 2019), French (Martin et al., 2020), Japanese Inui Laboratory (2019), Dutch (de Vries et al., 2019). In our experiments, we compare the performance of YiSi-1 using these monolingual models against that using multilingual language models.

Other monolingual models in English A number of modifications to BERT have been proposed to optimize the pretrained language models. Lan et al. (2020) proposed ALBERT to reduce the amount of parameters in BERT for lower memory consumption and faster training speed. BART (Lewis et al., 2019) is effective when fine tuned for text generation tasks. RoBERTa (Liu et al., 2019) is a more robustly trained version of BERT where the key hyperparameters are empirically chosen. XLNET (Yang et al., 2019) an autoregressive model that maximizes the expected likelihood over all permutations of the input sequence factorization order. We use these models in YiSi-1 for correlation analysis with human judgment on translation quality.

2.1.2 Multilingual models

In addition to multilingual BERT used in Lo (2019), XLM-RoBERTa (Conneau et al., 2020) (XLM-R) is also a massive multilingual pretrained language model. Similar to BERT, XLM-R is also trained with a masked language model task on the concatenation of non-parallel data. The differences between XLM-R and BERT are 1) XLM-R is trained on the CommonCrawl corpus which is significantly larger than the Wikipedia training data used by BERT; 2) instead of a uniform data sampling rate used in BERT, XLM-R uses a language sampling rate that is proportional to the amount of data available in the training set. Because of these differences, XLM-R performs better on low resource languages than multilingual BERT. XLM-R covers 100 languages. In this work, we use XLM-R$_{large}$ for the best performance on lexical semantic similarity.

2.2 Inuktitut-English Cross-lingual Language Model

Since Inuktitut is not covered by any publicly released pretrained language model, we trained our own Inuktitut-English XLM (Lample and Conneau, 2019) using the Nunavut Hansard 3.0 (NH) parallel corpus (Joanis et al., 2020). The model was trained with masked language model and translation language model tasks. The Inuktitut-English XLM model has 12 layers with 8 heads and embedding size of 512.

2.3 Model size and intermediate layers

In this study, we are interested in achieving the best performance using the pretrained language models. Thus, if different sizes of the same model architecture are released, we only evaluate the largest one in out experiment. As suggested by Devlin et al. (2018); Peters et al. (2018); Zhang et al. (2020), we experimented using contextual embeddings extracted from different layers of the multilingual language encoder to find out the layer that

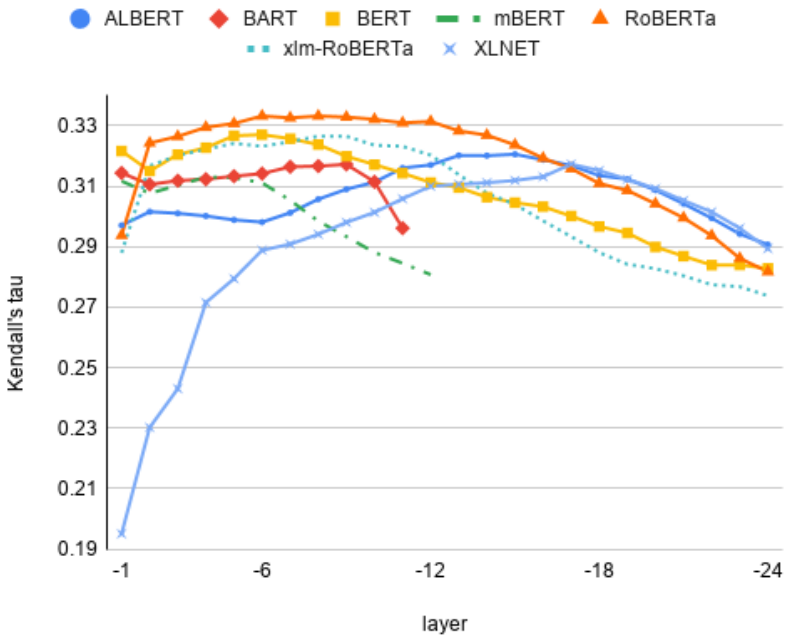

Figure 1: Average segment-level Kendall's τ correlation with human direct assessment on WMT19 *-en news translation test set of YiSi-1 using different pretrained language representation models. best represents the semantic space of the language.

3 Experiments and Results

We use WMT 2019 metrics shared task evaluation set (Ma et al., 2019) for our development experiments. The official human judgments for translation quality of WMT 2019 were collected using reference-based direct assessment.

Since we use exactly the same correlation analysis as the official metrics shared evaluation and the 2019 version of YiSi performed consistently well among participants in WMT 2019, we only compare our results with the 2019 version of YiSi and BLEU. Our results are directly comparable with those reported in Ma et al. (2019).

3.1 Architectures of monolingual English models

In Figure 1, we plot the change of segment-level Kendall's τ correlation of YiSi-1 across different layers of the monolingual and multilingual pretrained language models for evaluating English MT output. We see that YiSi-1 using RoBERTa$_{large}$ at layer -6 achieved the correlation with human translation quality judgment; marginally better than that using BERT$_{large}$ and XLM-RoBERTa$_{large}$. Therefore, in WMT 2020 metrics shared task *-English MT output evaluation, we submit YiSi-1 scores based on embeddings extracted from the layer -6 of RoBERTa$_{large}$.

3.2 Monolingual models vs. multilingual models

In Figure 1 and 2, we identify a common pattern that for evaluating English, Finnish, French and Chinese, using monolingual models (RoBERTa for English, CamemBERT for French and BERT for Finnish and Chinese) in YiSi-1 achieved the best correlation with human translation quality judgment. The only exception is using German BERT in YiSi-1 for evaluating German MT output where YiSi-1 using XLM-RoBERTa significantly outperforms that using German BERT. One of the possible reasons is that there is a domain mismatch between the training data of the German BERT and the MT output in the evaluation. The data used in the German BERT included 20% of legal documents while the MT output of WMT 2019 metrics shared evaluation set belongs to the news domain. Since YiSi-1 using monolingual BERT model usually outperforms that using multilingual pretrained

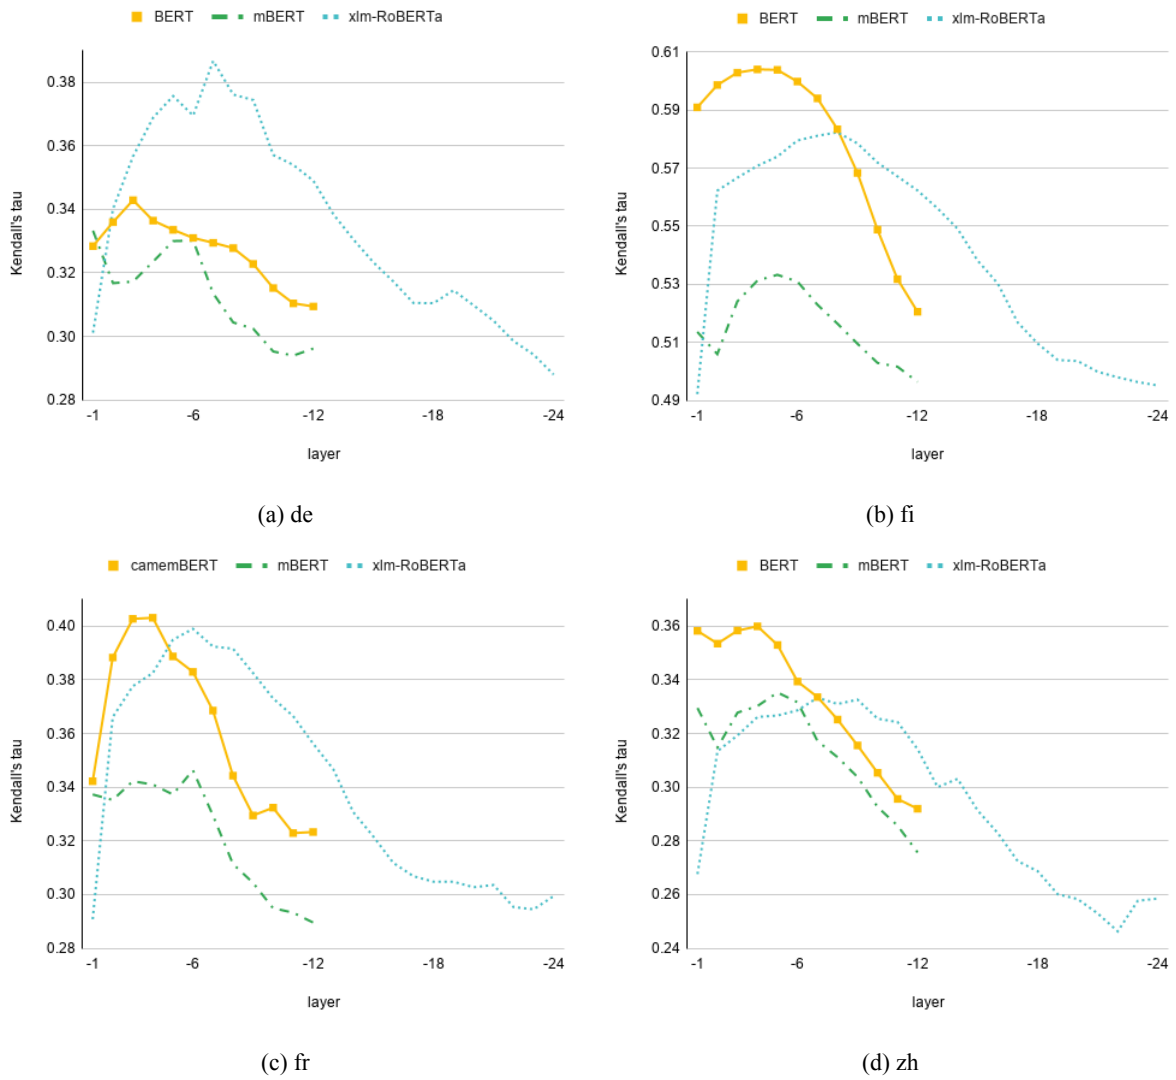

Figure 2: Average segment-level Kendall's τ correlation with human direct assessment on WMT19 (a) *-de, (b) en-fi, (c) de-fr and (d)en-zh news translation test set of YiSi-1 using different pretrained language representation models. Solid lines represent the use of pretrained monolingual models. Dotted line represents the use of pretrained XLM-R and dashed line represents the use of pretrained multilingual BERT.

language model, we believe that for evaluating MT output in WMT 2020 metrics shared task, using YiSi-1 with the monolingual BERT (while available, i.e. CamemBERT for French, BERT for Japanese and Chinese) would be a better model choice.

Another common pattern we see is that YiSi-1 using the monolingual BERT$_{base}$ model usually achieved the best correlation with human translation quality judgment at layer -4. Therefore, in WMT 2020 metrics shared task *-Chinese/French/Japanese MT output evaluation, we submit YiSi-1 scores based on embeddings extracted from the layer -4 of the corresponding monolingual BERT model.

3.3 Multilingual BERT vs. XLM-RoBERTa

In Figure 3, we plot the change of segment-level Kendall's τ correlation for YiSi-1 across different layers of XLM-R and multilingual BERT models for evaluating English-Czech/Gujarati/Kazakh/Lithuanian/Russian.
We identify a common trend, YiSi-1 using embeddings extracted from XLM-RoBERTa significantly outperforms YiSi-1 using embeddings extracted from multilingual BERT, except for evaluating Kazakh MT output where the gains of using XLM-RoBERTa is marginal. On average in all translation directions, the optimal layer of representation in XLM-R for YiSi-1 is layer -7.

YiSi-1 (2019)	.376	.349	.310
YiSi-0	.331	.296	.277

4 Improvements over previous version of YiSi-1

Table 1 and 2 show the Kendall' s τ correlation with the segment-level human direct assessment relative ranking on the WMT 2019 evaluation set. YiSi-1 (2020) shows consistent and significant improvements when comparing to the previous version of YiSi-1 across all translation directions.

Table 3 and 4 show the Person's ρ correlation with the system-level human direct assessment relative ranking on the WMT 2019 evaluation set. Although the improvements at system-level correlation is less consistent across different translation directions, YiSi-1 (2020) outperforms YiSi-1(2019) in the evaluation of two-third of all the tested translation directions.

5 Conclusion

We have presented an extend study of the pretrained language models used in YiSi-1 for machine translation evaluation. From this study, we conclude that for the best performance of YiSi-1: 1) when evaluating MT output in English, it is recommended to use the contextual embeddings extracted from layer -6 of RoBERTa$_{large}$; 2) when evaluating MT output in languages where monolingual pretrained model in the same or general domain is available, it is recommended to use the contextual embeddings extracted from those models; and finally 3) when evaluating MT output in languages only covered by multilingual pretrained language models, it is recommended to use the contextual embeddings extracted from layer -7 of XLM-RoBERTa.

This improved version of YiSi-1 is submitted to the WMT 2020 metrics shared task. For evaluating Inuktitut↔English where one of the language (Inuktitut) is not covered by any released pretrained langauge model, we build our own XLM cross-lingual language model with the parallel training data.

Abstract

We present a study on using YiSi-2 with massive multilingual pretrained language models for machine translation (MT) reference-less evaluation. Aiming at finding better semantic representation for semantic MT evaluation, we first test YiSi-2 with contextual embeddings extracted from different layers of two different pretrained models, multilingual BERT and XLM-RoBERTa. We also experiment with learning bilingual mappings that transform the vector subspace of the source language to be closer to that of the target language in the pretrained model to obtain more accurate cross-lingual semantic similarity representations. Our results show that YiSi-2's correlation with human direct assessment on translation quality is greatly improved by replacing multilingual BERT with XLM-RoBERTa and projecting the source embeddings into the target embedding space using a cross-lingual linear projection (CLP) matrix learnt from a small development set.

1 Introduction

The machine translation quality estimation as a metric (QE as a metric) task was first introduced in WMT 2019 (Ma et al., 2019; Fonseca et al., 2019) to encourage the exploration of reference-less evaluation metrics. QE as a metric task shifts the use case of the QE systems from assisting professional translators to estimate post-editing efforts to assisting MT developers or general MT users to discriminate the translation quality of different MT systems without the presence of a human reference translation. YiSi-2, the reference-less variants of the YiSi metric (Lo, 2019), was the only metric who participated in evaluating all the translation directions in WMT 2019 QE as a metric shared task.

The QE as a metric task is very similar to Task 1 (Sentence-level direct assessment) of WMT20's quality estimation shared task where metric performance is evaluated in terms of correlation at the sentence-level with human direct assessment scores on translation quality. The subtle but crucial difference between the WMT20 QE Task 1 and the QE as a metric task is that QE systems for the former task is trained specifically to estimate the quality of a single MT system whereas QE metrics for the latter task is generalized for multiple machine translation systems. The QE systems for WMT20's QE Task 1 have access to the MT system that generate the translations while the reference-less metrics for the latter task have no information on the MT systems being evaluated.

In WMT 2019 metrics shared task, pretrained multilingual BERT (Devlin et al., 2018) was used in YiSi for both MT reference-based (YiSi-1) and reference-less (YiSi-2) evaluation in all tested translation directions where monolingual pretrained BERT model was not available for the target language (such as Czech, German, etc.). Since then, another massive multilingual pretrained language model, XLM-RoBERTa (Conneau et al., 2020), has been published. We evaluate the use of contextual embeddings extracted from each of the intermediate layers of the two models in MT reference-less evaluation.

In addition, despite using the same pretrained embedding model of last year, YiSi-2 showed a significant performance degradation when comparing to YiSi-1. For example, segment-level correlation with human direct assessment for evaluating English→Czech drops from 0.475 (YiSi-1) to 0.069 (YiSi-2). This shows that the cross-lingual semantic representation in pretrained multilingual BERT is not as accurate as the monolingual semantic representation for each language. In other words, we observed the language clustering effect where a clear segregation of vector subspace among different languages in the multilingual contextual em-

Online, November 19–20, 2020.

bedding model. Inspired by Zhao et al. (2020), we employ a weakly-supervised bilingual mapping learnt from a small development set that transforms the contextual embeddings of the source sentence to the target subspace for better cross-lingual semantic similarity evaluation.

In this paper, we show that YiSi-2's correlation with human direct assessment on translation quality is greatly improved by replacing multilingual BERT with XLM-RoBERTa$_{large}$ using the optimal intermediate layer (7^{th} layer count from the last) and projecting the source embeddings into the target embedding space using a cross-lingual linear projection matrix learnt from a small development set.

2 YiSi-2

YiSi (Lo, 2019) is a unified semantic MT quality evaluation and estimation metric for languages with different levels of available resources. YiSi-1 measures the similarity between a machine translation and human references by aggregating weighted distributional (lexical) semantic similarities, and optionally incorporating shallow semantic structures. Improvements in YiSi-1 for WMT 2020 metrics shared task is detailed in (Lo, 2020).

YiSi-2 is the bilingual, reference-less version, which uses bilingual word embeddings to evaluate cross-lingual lexical semantic similarity between the input and MT output.

2.1 Massive Multilingual Pretrained Language Models

YiSi-2 relies on a cross-lingual language representation to evaluate the cross-lingual lexical semantic similarity. Previously, it used pretrained multilingual BERT (Devlin et al., 2018) for this purpose. BERT captures the sentence context in the embeddings, such that the embedding of the same subword unit in different sentences would be different from each other and be better represented in the embedding space. Since multilingual BERT is trained on the concatenation of non-parallel data from each language, the circular dependency deadlock between parallel resource and cross-lingual semantic similarity is broken (Lo and Simard, 2019). Multilingual BERT covers the 104 largest languages in Wikipedia.

XLM-RoBERTa (Conneau et al., 2020) (XLM-R) is also a massive multilingual pretrained language model. Similar to BERT, XLM-R is also trained with a masked language model task on the concatenation of non-parallel data. The differences between XLM-R and BERT are 1) XLM-R is trained on the CommonCrawl corpus which is significantly larger than the Wikipedia training data used by BERT; 2) instead of a uniform data sampling rate used in BERT, XLM-R uses a language sampling rate that is proportional to the amount of data available in the training set. Because of these differences, XLM-R performs better on low resource languages than multilingual BERT. XLM-R covers 100 languages. In this work, we use XLM-R$_{large}$ for the best performance on cross-lingual semantic similarity.

As suggested by Devlin et al. (2018); Peters et al. (2018); Zhang et al. (2020), we experimented using contextual embeddings extracted from different layers of the multilingual language encoder to find out the layer that best represents the semantic space of the language.

2.2 Inuktitut-English Cross-lingual Language Model

Since Inuktitut is neither covered by pretrained multilingual BERT nor XLM-RoBERTa, we trained our own Inuktitut-English XLM (Lample and Conneau, 2019) using the Nunavut Hansard 3.0 (NH) parallel corpus (Joanis et al., 2020). The model was trained with masked language model and translation language model tasks. The Inuktitut-English XLM model has 12 layers with 8 heads and embedding size of 512.

2.3 Cross-lingual Linear Projection

In the WMT 2019 metrics shared task (Ma et al., 2019), we saw a very significant performance degradation between YiSi-1 and YiSi-2. This shows that current multilingual language models construct a shared multilingual space in an unsupervised manner without any direct bilingual signal, in which representations of context in the same language are likely to cluster together in part of the subspace and there is a language segregation in the shared multilingual space. Inspired by Artetxe et al. (2016) and Zhao et al. (2020), we obtain subword token pairs from the news translation task development set for each language (each contains around 1k to 3k sentence pairs) aligned by maximum alignment of their semantic similarities. We then train a cross-lingual linear projection (Zhao et al., 2020) that transforms the source embeddings into the target embeddings subspace.

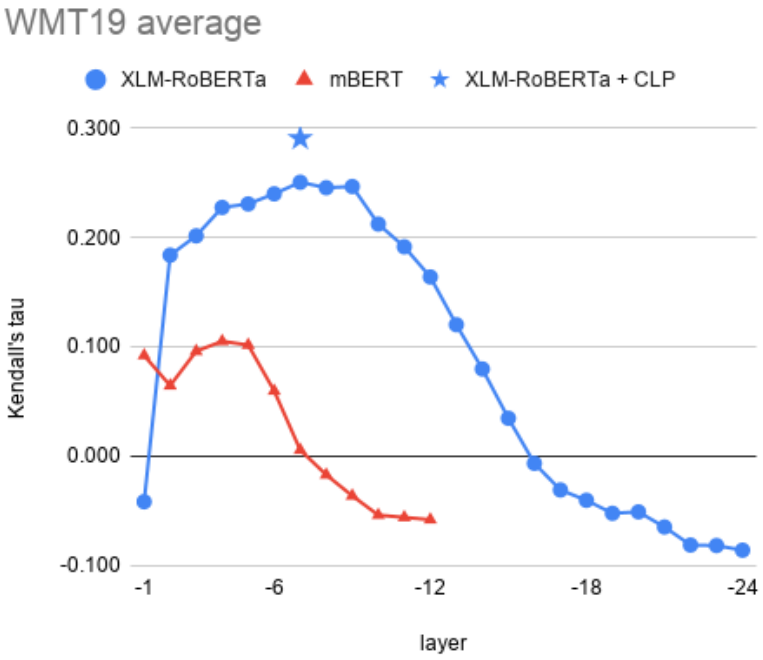

Figure 1: Segment-level Kendall's τ correlation with human direct assessment averaged over all WMT 2019 news translation test sets of YiSi-2 using contextual embeddings extracted from different layers of the multilingual pre-trained language models. On the x-axis, layer $-n$ means, YiSi-2 based on the embeddings of the n^{th} layer, counting from the last, of XLM-RoBERTa$_{large}$ (blue circles), multilingual BERT (red triangles) and layer -7 of of XLM-RoBERTa$_{large}$ with source embeddings projected to target language space using CLP (blue star).

3 Results

We use WMT 2019 metrics task evaluation set (Ma et al., 2019) for our development experiments. The official human judgments for translation quality of WMT 2019 were collected using reference-based direct assessment.

Since we use exactly the same correlation analysis as the official metrics shared evaluation and the 2019 version of YiSi performed consistently well among participants in WMT 2019, we only compare our results with the 2019 version of YiSi and BLEU. Our results are directly comparable with those reported in Ma et al. (2019).

3.1 Segment-level correlation with human judgment

In Figure 1, 2, 3 and 4, we plot the change of segment-level Kendall's τ correlation for YiSi-2 across different layers of XLM-R and multilingual BERT models. We identify a common trend, YiSi-2 using embeddings extracted from XLM-R significantly outperforms YiSi-2 using embeddings extracted from multilingual BERT. From figure 1, we see that, on average, on all translation directions, the optimal layer of representation in XLM-R for YiSi-2 is layer -7. Learning the cross-lingual linear projection matrix to transform the source embeddings into the target language subspace shows a greater improvement overall. This is our "YiSi-2 (2020)" submission to the QE as a metric task.

Table 1 and 2 show the Kendall's τ correlation with the segment-level human direct assessment relative ranking on the WMT 2019 evaluation set. YiSi-2 (2020) shows consistent and significant improvements when comparing to the previous version of YiSi-2 across all translation directions.

Although YiSi-2 (2020) still performs worse than YiSi-1, YiSi-2 (2020) correlates better with human judgment than the reference-based metric, sentBLEU, and its performances are comparable to those of the character-based YiSi variant, YiSi-0, on evaluating translation quality for most of the translation directions.

3.2 Correlation with human judgment at system level

Table 3 and 4 show the Person's ρ correlation with the system-level human direct assessment relative ranking on the WMT 2019 evaluation set.

Similar to the segment-level results, although YiSi-2 (2020) still performs significantly worse than YiSi-1, we observe significant improvements, compared to the previous version of YiSi-2, consistently across all translation directions. We also show that by replacing the multilingual BERT with XLM-R and using bilingual mappings to better align the source and target language subspaces in XLM-R, YiSi-2 (2020) correlates better with human judgment than the reference-based metric, BLEU, on evaluating translation quality for most of the translation directions.

4 Conclusion

We have presented an improved version of YiSi-2 that uses XLM-RoBERTa and a cross-lingual linear projection of the source embedding to the target language subspace to better capture the semantic representation across languages. Our results show that YiSi-2 correlates better with human judgement on evaluating translation quality than BLEU for most of the evaluation conditions. This improved version of YiSi-2 is submitted to the WMT 2020 Metrics shared task QE as a metric track. For evaluating Inuktitut↔English where one of the language (Inuktitut) is not covered by XLM-R, we build our own XLM cross-lingual language model with the parallel training data. Potential research directions definitely include improving massive multilingual pretrained language model to close the performance gap between YiSi-1 and YiSi-2 and expanding the language coverage of these models in post-hoc and unsupervised manner.

Unbabel's Participation in the WMT20 Metrics Shared Task

Ricardo Rei **Craig Stewart** **Ana C Farinha** **Alon Lavie**
Unbabel AI
{ricardo.rei, craig.stewart, catarina.farinha, alon.lavie}@unbabel.com

Abstract

We present the contribution of the Unbabel team to the WMT 2020 Shared Task on Metrics. We intend to participate on the segment-level, document-level and system-level tracks on all language pairs, as well as the "QE as a Metric" track. Accordingly, we illustrate results of our models in these tracks with reference to test sets from the previous year. Our submissions build upon the recently proposed COMET framework: we train several estimator models to regress on different human-generated quality scores and a novel ranking model trained on relative ranks obtained from Direct Assessments. We also propose a simple technique for converting segment-level predictions into a document-level score. Overall, our systems achieve strong results for all language pairs on previous test sets and in many cases set a new state-of-the-art.

1 Introduction

In this paper we describe our submission to the WMT20 Metrics shared task. Our work is based on the COMET[1] framework, as presented in Rei et al. (2020), and extended here to evaluation of MT output at segment, document and system-level, forming the basis of our submissions to the corresponding task tracks. Recently, automatic evaluation of MT has followed most other sub-fields in NLP with a notable interest in leveraging the power of large, pre-trained language models. Metrics such as BERT REGRESSOR (Shimanaka et al., 2019), BERTSCORE (Zhang et al., 2020), BLEURT (Sellam et al., 2020) and our more recent COMET (Rei et al., 2020), all build upon developments in language modelling to generate automatic metrics with high correlation with human judgement. Our MT evaluation models follow a similar strategy, specifically utilizing the most recent iterations of the XLM-RoBERTa model presented in Conneau et al. (2020).

The uniqueness of our approach comes from our inclusion of the source text as input which was demonstrated in Takahashi et al. (2020) and Rei et al. (2020) to be beneficial to the model. In our contribution to the shared task, we demonstrate methods of further exploiting information in the source text as well as a technique to fully harness the power of pre-trained language models to further improve the prediction accuracy of our evaluation framework when more than one reference translation is available.

For the shared task, we utilize two primary types of models built using the COMET framework, namely; the Estimator models, which regress directly on human scores of MT quality such as Direct Assessment; and the COMET-RANK (base) model used to rank MT outputs and systems.

In addition to the models themselves, we also make the following research contributions:

1. We introduce a method for handling multiple references at inference time and for optimizing the utility of information from all available text inputs

2. We propose a simple technique for calculating a document-level score from a weighted average of segment-level scores

We demonstrate that our COMET framework trained models achieve state-of-the-art results or are competitive on all settings introduced in the WMT19 Metrics shared task, outperforming, in some cases, more recently proposed metrics such as BERTSCORE (Zhang et al., 2020), BLEURT (Sellam et al., 2020) and PRISM (Thompson and Post, 2020).

2 The COMET Framework

As outlined in Rei et al. (2020), the COMET framework allows for training of specialized evaluation metrics that correlate well with different types of human-generated quality scores. The general structure of the framework consists of a cross-lingual encoder that produces a series of token-level vector embeddings for source, hypothesis and reference inputs, a pooling layer which converts the various token-level representations into segment-level vectors for each input, and a predictive neural network that generates a quality score. The latter model can either be trained to regress directly on a score to produce predictions of segment-level quality, or can be trained as a ranker to differentiate MT systems. In our contribution to the shared task, we introduce two varieties of models built on the COMET framework that are extensions of the models evaluated in Rei et al. (2020).

3 COMET Models

3.1 Estimator Models

Our Estimators generally follow the architecture proposed in Rei et al. (2020), that is to say we encode segment-level representations using XLM-RoBERTa and pass these outputs through a feed-forward regressor. As in Rei et al. (2020), we train three versions of this basic estimator model against different types of human judgement; *Human-mediated Translation Edit Rate* (HTER) (Snover et al., 2006), a proprietary implementation of *Multidimensional Quality Metric* (MQM) (Lommel et al., 2014) and (in-line with the present task) *Direct Assessments* (DA) (Graham et al., 2013). The hyper-parameters used for these models are exactly as described in Rei et al. (2020), excluding the following alterations: we use XLM-RoBERTa large instead of base and we increase the feed-forward hidden sizes (from 2304 in the first layer and 1152 in the second to 3072 and 1536 hidden units, respectively). We also keep the embedding layer frozen and apply a layer-wise learning rate decay (as proposed in Howard and Ruder (2018)) by which each transformer layer has a learning rate scaled at 0.95 times the rate of the layer above. By doing this, we hope that our metric generalizes better to new language pairs introduced this year.

3.2 Translation Ranking Model

While for the Estimators using a larger pretrained encoder seems to improve performance we found that for the Translation Ranking Model, larger pretrained encoders lead to training instability and an overall worse performance. For that reason we decided to keep the model proposed in (Rei et al., 2020) without any alteration.

4 Corpora

Below we provide an outline of the various datasets used to train our models:

4.1 HTER Corpora

Our HTER corpus is a concatenation of two publicly available corpora: the QT21 corpus and the APE-QUEST corpus. While the QT21 corpus contains segments from the information technology and life sciences domains (Specia et al., 2017), the APE-QUEST contains segments from the legal domain (Ive et al., 2020). Concatenation of these two corpora gives a total of 211K tuples with source sentence, corresponding human-generated reference, MT hypothesis, and post-edited MT (PE). With regard to the language pairs in each corpus, QT21 covers: English to German (en-de), Latvian (en-lt) and Czech (en-cs), and German to English (de-en); while APE-QUEST covers: English-Dutch (en-nl), English-French (en-fr), English-Portuguese (en-pt). Finally, the HTER score is obtained by calculating the translation edit rate (TER) (Snover et al., 2006) between the MT hypothesis and the corresponding PE. By doing this, we were able to create a large HTER corpus covering several language pairs and different domains.

4.2 MQM Corpus

Our MQM corpus is an extension of the proprietary corpus presented in Rei et al. (2020). This internal data consists of customer support chat messages translated using a domain adapted MT model and their corresponding references (consisting of post-edited translations from earlier iterations of the MT systems). The data was then MQM-annotated according to the guidelines set out in Burchardt and Lommel (2014). Our final corpus contains 27K tuples from English into 15 different languages and/or dialects: German (en–de), Spanish (en–es), Latin-American Spanish (en–es-latam), French (en–fr), Italian (en–it), Japanese (en–ja), Dutch (en–nl), Portuguese (en–pt), Brazilian Portuguese (en–pt-br), Russian (en–ru), Swedish (en–sv), Turkish (en–tr), Polish (en–pl), simplified Chinese (en–zh-CN), and Taiwanese Chinese (en–zh-TW).

4.3 DA Corpora

Every year, since 2008, the WMT News Translation shared task organizers collect human judgements in the form of DAs. Since 2017, due to a lack of annotators, these scores are mapped to relative rankings (DARR). We take advantage of this data in two ways: 1) we use the scores directly in order to train an estimator model, 2) as in Rei et al. (2020), we use the DARR to train a translation ranking system. The collective corpora of 2017, 2018 and 2019 contain a total of 24 language pairs, including low-resource languages such as English-Gujarati (en-gu) and English-Kazakh (en-kk). For the purposes of this paper we use the data from 2017 and 2018 to train and the data from 2019 to validate. Later, for participation in the 2020 shared task, we intend to include the data from 2019 in our training corpus.

5 Segment-Level Task

At segment-level, we take each of our Estimator models trained to predict MQM, HTER and DA and predict segment-level scores on the DARR data from WMT19. We then generate pairwise rankings based on these predicted scores. For each language pair we apply the formulation of Kendall's Tau (τ) from the shared task (Ma et al., 2019) as follows:

$$\tau = \frac{\textit{Concordant} - \textit{Discordant}}{\textit{Concordant} + \textit{Discordant}} \quad (1)$$

Concordant here being the number of times a metric assigns a higher score to the "better" hypothesis h^+ and *Discordant*, the number of times a metric assigns a higher score to the "worse" hypothesis h^-, or that the evaluation was otherwise equal.

6 Document-Level Task

In the WMT2019 News Translation the organizers introduced a document-level translation task (Barrault et al., 2019) for en-de and en-cs. This means that for those language pairs we are able to obtain document-level direct assessments. We can compute a score taking into account an entire document and correlate it with the human evaluation also carried out at document-level.

For our document-level submission we propose the generation of a document-level score as a weighted average of the predicted scores for each segment composing that document (hereinafter called micro-average score), where the same is weighted by segment length.

To calculate this score at inference time we pass the entire document (divided into segments) through the model as a single batch. This has the added effect of reducing inference time.

7 System-level Task

Following previous years, the metric used in the System-level Task will be Pearson's r correlation score. The correlation is calculated between the average of all DA human z-scores for a given system and language pair, and the average of the corresponding scores predicted by a given metric. Because the goal of some metrics is to maximize the correlation with human judgements (i.e. BLEU), while for others is to minimize that correlation (i.e. HTER), the value reported is its absolute value.

7.1 Robustness to high-permorming systems

One important finding from WMT19 is the general deterioration of metrics' performance when considering only the top n MT systems (Ma et al., 2019). Previously, we showed robustness of our metrics in this scenario in terms of Kendall's Tau at segment-level (Rei et al., 2020). Mathur et al. (2020) show that at system-level, Pearson correlation is highly influenced by outliers and that performances for metrics such as BLEU drop significantly when considering only the top systems. To address this, we propose a system-level pairwise comparison measured with the same Kendall's Tau formulation used for segment-level analysis outlined in section 5 above. By doing this, we are not only better handling possible outliers, but emulating a real world application of these metrics: In most cases (both in academia and industry), we want a metric that can successfully differentiate between two systems, even if those systems are very close in terms of performance, which is often the case.

8 Quality Estimation as a Metric

Given the clear parallels between the COMET framework and modern approaches to Quality Estimation such as Kepler et al. (2019), we used our framework to participate in the "QE as a Metric" track of the shared task by removing the reference at input and proportionately reducing the dimensions of the feed-forward network to accommodate the reduced input.

Table 1: Segment-level Kendall's Tau (τ) correlations for language pairs from English-to-other for the WMT19 Metrics DARR corpus.

9 Multi-Reference Handling

In this year's shared task we are provided with a second human-generated reference for German-to-English (de-en), Russian-English (ru-en) and Chinese-to-English (zh-en). Given that our base framework currently supports the input of only one single reference, we introduce a method of leveraging information from a second reference at inference time.

During standard training of our models, we input source, hypothesis and reference in that order, resulting in a concatenation of embeddings as detailed further in Rei et al. (2020). During training, with a probability of $p = 0.5$ we switch the positions of source and reference, such that the system receives the reference as the source and vice versa. This has two primary effects on our model. Firstly, during fine-tuning of the underlying language model, the source embeddings are aligned with the target language embedding space resulting in more useful source embeddings. Secondly, it forces the model to treat source and reference as interchangeable inputs, allowing it to handle switching of inputs at inference time without excessively hindering the model's predictive ability. Finally, at inference time we embed source $\boldsymbol{s}$, hypothesis $\boldsymbol{h}$, reference $\boldsymbol{r}$ and the alternative reference $\hat{\boldsymbol{r}}$. These embeddings are then passed to the feed-forward neural network in the following six permutations: $[\boldsymbol{s}; \boldsymbol{h}; \boldsymbol{r}]$, $[\boldsymbol{r}; \boldsymbol{h}; \boldsymbol{s}]$, $[\boldsymbol{s}; \boldsymbol{h}; \hat{\boldsymbol{r}}]$, $[\hat{\boldsymbol{r}}; \boldsymbol{h}; \boldsymbol{s}]$, $[\boldsymbol{r}; \boldsymbol{h}; \hat{\boldsymbol{r}}]$ and $[\hat{\boldsymbol{r}}; \boldsymbol{h}; \boldsymbol{r}]$.

Six passes through the feed-forward gives us six predictions. Final, aggregated scores are achieved by taking the mean of the six predictions and multiplying it by 1 minus the standard deviation (σ). The intuition being that $1 - \sigma$ gives something of an idea of confidence of the model at the segment-level and that scaling the mean prediction to penalize lower confidence might align better with human judgement.

10 Experimental Results

Below we present results of our various COMET models on WMT19 evaluation sets as described

Table 3: Kendall's Tau (τ) correlation and standard deviation (σ) across all language pairs for the top 5 high-performing systems.

Model	Avg. Kendall (all)	Avg. Kendall (en)
BLEU	0.387±0.366	0.257±0.395

COMET-DA (large)	**0.653±0.233**	**0.629±0.269**
COMET-RANK (base)	0.547±0.256	0.543±0.276

above. Segment-level and document-level results are outlined in the corresponding tables within the body of the paper, the remaining tables for other task results are contained in the Appendices hereto.

10.1 Segment-level Task

Our segment-level results on the shared task test sets for WMT19 are detailed in tables 1 and 2. We note that for all language pairs out of English (Table 1) both our DA Estimator and our COMET-RANK (base) outperform prior metrics, in some cases by a significant margins. The same can be said in most language pairs into English, where we consistently perform at the level competitive with or exceeding prior metric performance in this task. Table 6 (contained in the appendices) further illustrates performance of our models on non-English language pairs. We note that in all settings our COMET models outperform state-of-the-art for these language pairs.

10.2 System-level Task

System-level results are outlined in tables 7, 8 and 9 in the appendix. In most language pairs we outperform the best metrics in terms of correlation with human judgement. For those language pairs for which our metrics are outperformed by others, we note that ours are at least competitive with other, recent metrics.

An unexpected result is that at system-level our COMET-RANK (base) does not perform as well as our Estimators, regardless of its strong segment-level results. We believe that this is an artifact of training directly on DARR data. Since in WMT shared tasks, the DA rating scale employed is defined at the 0-25-50-75-100 point margins, the minimum required difference between two hypothesis to produce DARR judgement is 25 points (Ma et al., 2019). All other segments are discarded, as within that range the notion of which hypothesis is better becomes ambiguous. As a result we believe that our ranker model learns to successfully discriminate less ambiguous examples and struggles to correctly assign a score otherwise.

10.2.1 Robustness to high-performing systems

As outlined above, we also complement our evaluation at system-level with an analysis of metric performance in terms of the pairwise ranking of the top five performing systems from each language pair. For each setting we output the Kendall's Tau (that is to say the formulation outlined in section 5 above) and report the mean and standard deviation of results across language pairs in table 3.

In both settings we note that our DA Estimator (large) model significantly outperforms other metrics both in terms of mean and standard deviation. This strongly suggests that not only do we perform well in terms of system-level Pearson but that at a practical level, our model can much more successfully differentiate high-performing systems.

10.3 Document-level Task

Table 10 compares the micro-averaging against a simple unweighted average. From table 10 we can observe that micro-averaging outperforms macro-averaging by a small margin. Table 4 summarizes our results for the Document-level Task using our segment-level Estimators with micro-averaging. In this task, the HTER Estimator shows generally superior performance on average surpassing our best performing segment-level model, the DA Estimator. An important conclusion to draw from the strong document-level correlations noted here is that a

model trained to generate segment-level scores, can also perform well as a document-level metric.

Table 4: Pearson correlation (r) between Document-level DAs and micro average segment-level scores for English-to-German and English-to-Czech.

	en-cs	**en-de**	
Nº Documents	1115	2355	**avg.**
COMET-MQM (large)	0.638	0.516	0.577
COMET-HTER (large)	0.655	**0.558**	**0.607**
COMET-DA (large)	**0.667**	0.528	0.598

Table 5: Pearson correlations (r) and adequacy (as reported in Freitag et al. (2020)) for segment-level DA using our DA Estimator (large) model on WMT19 Metrics shared task test data for en-de. We show Pearson's r for the single reference scenario using the corresponding reference ('1-ref') and the multi-reference scenario where the reference is combined with the original in the manner outlined in section 9 above ('2-ref').

Reference	**Adequacy**	r **(1-ref)**	r **(2-ref)**
WMT	85.3	0.523	-
AR	86.7	0.539	0.555
WMTp	81.8	0.470	0.529
ARp	80.8	0.476	0.537

10.4 Multi-Reference Handling

Additional references were obtained for two language pairs: en-de and de-en. For the former, we conducted experiments using 3 additional references from Freitag et al. (2020): AR reference (an additional high quality reference translation), ARp reference (a paraphrased-as-much-as-possible version of AR), and WMTp reference (a paraphrased-as-much-as-possible version of the original WMT reference); for the latter, we use the alternative reference given in the WMT19 News shared task test set. Conveniently, Freitag et al. (2020) also offer a notion of the quality of the extra references for en-de by providing human-generated adequacy assessments for each. In table 5 we show the performance of our DA Estimator (large) model with each reference, either as a single reference or combined in the manner described in section 9 above with the original reference.

While we lack data to draw any statistically significant conclusions, there is a strong suggestion from these results of a positive correlation between reference quality and utility to the predictive model.

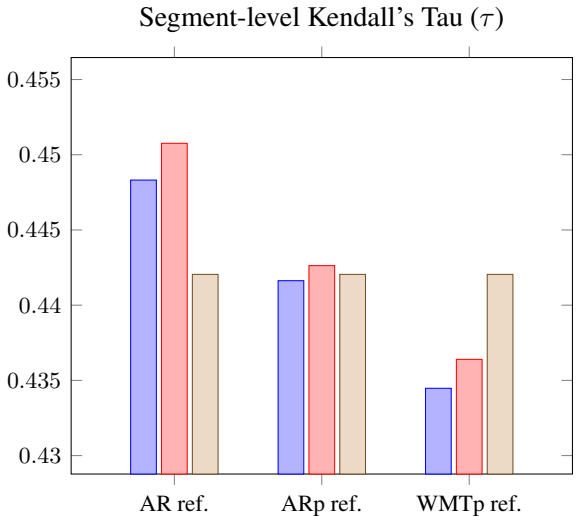

Figure 1: Performance impact of using different kinds of references in combination with the original WMT English-to-German reference. In — we observe the Kendall-Tau τ ranking correlation achieved by our multi-reference Estimator model (section 9). In — we present the Kendall-Tau τ ranking correlation of our "one-reference" Estimator model using the alternative reference. Finally, for comparison, in — we show the Kendall-Tau τ ranking correlation of our "one-reference" Estimator model using the original reference.

For de-en, using an alternative reference did not offer any gain in Pearson's r. We note that when using it alone we only achieve r=0.34 compared to using the original reference which achieves r=0.42. We speculate, based on our observations above, that this might be due to the alternative reference being of lower quality.

These results potentially show that for approaches such as COMET, quality is more important than quantity, and that lower-quality additional references can potentially hurt rather than help improve the correlations obtained using only one single high-quality reference.

With regard to the Kendall Tau measured at segment-level, by looking at Figure 1 (en-de), we see no significant differences in using the multi-reference technique. This suggests that having a higher Pearson's r score does not necessarily guarantee a better Kendall's Tau.

We note that by design, with an approach such as COMET that is based on a meaning-representation of references, extra references are expected to provide only minor additional value, especially versus lexical-based metrics such as BLEU (Papineni et al., 2002). Whereas the adequacy of the reference(s)

is (again by design) expected to have a more significant impact on the performance of the model. Our initial results seem to strongly support this hypothesis.

11 Conclusions

In this paper we present COMET, Unbabel's contribution to the WMT 2020 Metrics shared task. We leverage the framework outlined in Rei et al. (2020) to demonstrate state-of-the-art or otherwise competitive levels of correlation with human judgements in all tasks and introduce a novel method of making optimal use of alternative references and demonstrate that the quality of the reference used is relevant to the success of our framework. Further investigation of the latter, in particular how to better leverage different kinds of references, represent an interesting direction for future work.

12 Acknowledgments

We are grateful to Fabio Kepler, Daan Van Stigt, Miguel Vera, and the reviewers, for their valuable feedback and discussions. This work was supported in part by the P2020 Program through projects MAIA and Unbabel4EU, supervised by ANI under contract numbers 045909 and 042671, respectively.

Learning to Evaluate Translation Beyond English
BLEURT Submissions to the WMT Metrics 2020 Shared Task

Abstract

The quality of machine translation systems has dramatically improved over the last decade, and as a result, evaluation has become an increasingly challenging problem. This paper describes our contribution to the WMT 2020 Metrics Shared Task, the main benchmark for automatic evaluation of translation. We make several submissions based on BLEURT, a previously published metric which uses transfer learning. We extend the metric beyond English and evaluate it on 14 language pairs for which fine-tuning data is available, as well as 4 "zero-shot" language pairs, for which we have no labelled examples. Additionally, we focus on English to German and demonstrate how to combine BLEURT's predictions with those of YISI and use alternative reference translations to enhance the performance. Empirical results show that the models achieve competitive results on the WMT Metrics 2019 Shared Task, indicating their promise for the 2020 edition.

1 Introduction

The recent progress in machine translation models has led researchers to question the use of n-gram overlap metrics such as BLEU, which focus solely on surface-level aspects of the generated text, and thus may correlate poorly with human evaluation (Papineni et al., 2002; Lin, 2004; Ma et al., 2019; Mathur et al., 2020; Belz and Reiter, 2006; Callison-Burch et al., 2006). This has led to a surge of interest for more flexible metrics that use machine learning to capture semantic-level information (Celikyilmaz et al., 2020). Popular examples of such metrics include YISI-1 (Lo, 2019), ESIM (Mathur et al., 2019), BERTSCORE (Zhang et al., 2020), the Sentence Mover's Similarity (Zhao et al., 2019; Clark et al., 2019), and BLEURT (Sellam et al., 2020). These metrics utilize contextual embeddings from large models such as BERT (Devlin et al., 2019) which have been shown to capture linguistic information beyond surface-level aspects (Tenney et al., 2019).

The WMT Metrics 2020 Shared Task is the reference benchmark for evaluating these metrics in the context of machine translation. It tests the evaluation of systems that are to-English (X $\rightarrow$ En) and to other languages (X $\rightarrow$ Y), which requires a multilingual approach. An additional challenge for learned metrics is that human ratings are not available for all language pairs, and therefore, the models must use unlabeled data and perform zero-shot generalization.

We describe several learned metrics based on BLEURT (Sellam et al., 2020), originally developed for English data. We first extend BLEURT to the multilingual setup, and show that our approach achieves competitive results on the WMT Metrics 2019 Shared Task.[1] We also present several simple BERT-based baselines, which we submit for analysis. Finally, we focus on English to German and enhance BLEURT's performance by combining its predictions with those of YISI (Lo, 2019) as well as by using alternative references.

2 Background and Notations

Task Reference-based NLG evaluation seeks to assign a score to a triplet of sentences *(input, reference, candidate)*, where *input* is a sentence in the source language, *reference* is a reference translation kept secret at inference time, and *candidate* is a translation produced by an MT system.

[*] Work done during a summer internship. Permanent email address: amy_pu@brown.edu.

[†] Work done as a member of the Google AI Residency Program.

[1] We use the following languages for fine-tuning and/or testing: Chinese, Czech, German, English, Estonian, Finnish, French, Gujarati, Kazakh, Lithuanian, Russian, and Turkish. In addition, we also pre-train on Inuktitut, Japanese, Khmer, Pastho, Polish, Romanian, and Tamil.

Proceedings of the 5th Conference on Machine Translation (WMT), pages 921–927
Online, November 19–20, 2020.

Similar to BLEU (Papineni et al., 2002) and the previous editions of the WMT Metrics shared task, we omit the input and treat the task as a regression problem : we aim to learn a function $\boldsymbol{f} : (\boldsymbol{x}, \tilde{\boldsymbol{x}}) \rightarrow y$ that predicts a quality score y for a candidate sentence $\tilde{\boldsymbol{x}} = (\tilde{x}_1, .., \tilde{x}_p)$ given a reference sentence $\boldsymbol{x} = (x_1, .., x_q)$. The function is supervised on a corpus of N human ratings $\{(\boldsymbol{x}_i, \tilde{\boldsymbol{x}}_i, y_i)\}_{n=1}^{N}$.

BLEURT Most experiments presented in this paper are based on BLEURT, a metric that leverages transfer learning to achieve high accuracy and increase robustness (Sellam et al., 2020). BLEURT is a BERT-based regression model (Devlin et al., 2019). It embeds sentence pairs into a fixed-width vector $\boldsymbol{v}_{\text{BERT}} = \text{BERT}(\boldsymbol{x}, \tilde{\boldsymbol{x}})$ with a pre-trained Transformer, and feeds this vector to a linear layer:

$$\hat{y} = \boldsymbol{f}(\boldsymbol{x}, \tilde{\boldsymbol{x}}) = \boldsymbol{W}\boldsymbol{v}_{\text{BERT}} + \boldsymbol{b}$$

where $\boldsymbol{W}$ and $\boldsymbol{b}$ are the weight matrix and bias vector respectively.

In its original (English) version, BLEURT is trained in three stages. (1) It is initialized from a publicly available BERT checkpoint. (2) The model is then "warmed up" by exposing it to millions of sentence pairs $(\boldsymbol{x}, \tilde{\boldsymbol{x}})$, obtained by randomly perturbing sentences from Wikipedia. During this phase, the model learns to predict a wide range of similarity scores that include existing metrics (BERTSCORE, BLEU, ROUGE), scores from an entailment model, and the likelihood that $\tilde{\boldsymbol{x}}$ was generated from $\boldsymbol{x}$ with a round-trip translation by a given translation model. We denote this stage as *mid-training*. (3) In the final stage, the model is fine-tuned on human ratings from WMT Metrics (Bojar et al., 2017; Ma et al., 2018, 2019), using a regression loss $\ell_{\text{supervised}} = \frac{1}{N}\sum_{n=1}^{N} \|y_i - \hat{y}\|^2$. We found that English BLEURT achieved competitive performance on four academic datasets, WebNLG (Gardent et al., 2017), and the WMT Metrics Shared Task years 2017 to 2019.

3 Extending BLEURT Beyond English

3.1 Modeling

An approach to extend BLEURT would be to use MBERT, the public version of BERT pre-trained on 104 languages, and "mid-train" with non-English signals as described above. Yet, the evidence we gathered from early experiments were inconclusive. On the other hand, we did observe that models trained on several languages were often more accurate than monolingual models, possibly due to the larger amount of fine-tuning data. Thus, we opted for a simpler approach where we start with a multilingual BERT model and fine-tune it on all the human ratings data available for all languages (`X` $\rightarrow$ `Y` and `X` $\rightarrow$ `En`). In most cases, we found that such models could perform zero-shot evaluation: if a language `Y` does not have human ratings data, the metric can still perform evaluation in this target language as long as the base multilingual BERT model contains unlabeled data for `Y`, as observed in the past literature (Karthikeyan et al., 2019; Pires et al., 2019).

We experiment with two pre-trained multilingual models: MBERT and MBERT-WMT, a custom multilingual variant of BERT. The MBERT-WMT model is larger that MBERT (24 Transformer layers instead of 12), and it was pre-trained on 19 languages of the WMT Metrics shared task 2015 to 2020.

Details of MBERT-WMT pre-training We trained MBERT-WMT model with an MLM loss (Devlin et al., 2019), using a combination of public datasets: Wikipedia, the WMT 2019 News Crawl (Barrault et al.), the C4 variant of Common Crawl (Raffel et al., 2020), OPUS (Tiedemann, 2012), Nunavut Hansard (Joanis et al., 2020), WikiTitles[2], and ParaCrawl (Esplà-Gomis et al., 2019). We trained a new WordPiece vocabulary (Schuster and Nakajima, 2012; Wu et al., 2016), since the original vocabulary of mBERT does not support the alphabets of Pashto, Khmer and Inuktitut. The model was trained for 1 million steps with the LAMB optimizer (You et al., 2020), using the learning rate 0.0018 and batch size 4096 on 64 TPU v3 chips.

3.2 Experimental Setup

Datasets At the time of writing, no human ratings data is available for WMT Metrics 2020. Therefore, we use the human ratings from WMT Metrics years 2015 to 2019 for both training and evaluation. We do so in two stages. In the first stage, we use 2015 to 2018 for training (216,541 sentence pairs in 8 languages), setting 10% aside for early stopping. We use 2019 as a development set, to choose hyper-parameters and to

[2] https://linguatools.org/tools/corpora/wikipedia-parallel-titles-corpora/

support high-level modeling decisions. In the second stage, we use 2015 to 2019, that is, all the data available, for training and uniformly sample 10% of the data for early stopping and hyper-parameter tuning. This adds 289,895 sentence pairs and 4 additional languages to our training set, approximately doubling the size of the training data. We report our results on the first setup, but submit our predictions to the shared task using the second setup.

Hyper-parameters We run grid search on the learning rate and export the best model, using values {5e-6, 8e-6, 9e-6, 1e-5, 2e-5, 3e-5}. We use batch size 32 and evaluate the model every 1,000 steps on a 10% held-out data set to prevent over-fitting. During preliminary experiments, we additionally experimented with the batch size, dropout rate, frequency of continuous evaluation, balance of languages, pre-training schemes, WordPiece vocabularies, and model architecture.

3.3 Additional Models and Baselines

English BLEURT We fine-tune a new BLEURT checkpoint, following the methodology described above. The main difference with Sellam et al. (2020) is that we incorporate the to-English ratings of year 2019, which were not previously available.

Monolingual baselines based on BERT We experiment with three baselines and submit the results to the WMT Metrics Shared Task for analysis. BERT-L2-BASE and BERT-L2-LARGE are two regression models based on BERT and trained on to-English ratings. We use the same setup as English BLEURT, but we omit the mid-training phase. A similar approach was described in Shimanaka et al. (2019). BERT-CHINESE-L2 is similar to BERT-L2-BASE, but it uses BERT-CHINESE and it is fine-tuned on to-Chinese ratings.

Other Systems We compare our setups to other state-of-the-art learned metrics: BERTSCORE (Zhang et al., 2020), and Yisi (Lo, 2019) all apply rules on top of BERT embeddings while ESIM (Mathur et al., 2019) is a neural sentence similarity model. PRISM (Thompson and Post, 2020) trains a multilingual translation model that is used as a zero-shot paraphrasing system. All the aforementioned systems take sentences pairs as input. Concurrent work has investigated incorporating the source with great success (Rei et al., 2020). We leave this line of research for future work.

4 Results

Tables 1 and 2 show the results in the X → En direction, at the segment- and system-level respectively. In the majority of cases, one of the BLEURT configurations yields the strongest results. The original BLEURT metric seems to perform better at the segment-level. At the system-level it may be dominated by PRISM (3 out of 7 language pairs) or by one of the simpler BERT-based models (4 out of 7 language pairs).

Tables 3 and 4 present the results for the other languages. MBERT-WMT yields solid results at the segment-level (it achieves the highest correlations for 7 out of 11 language pairs), in particular for the "zero-shot" setups, En → Gu, En → Kk, and En → Lt. It outperforms MBERT consistently, except for En → Ru and En → Zh where it lags behind the other metrics. The results are consistent at the system-level.

Strategy for the WMT Metrics Shared Task Based on these results, we make two "competitive" submissions. We present BLEURT as described above, which we ran on all the X → En sentence pairs. Additionally, we submitted a multilingual system that combines MBERT-WMT (for all languages except Chinese) and BERT-CHINESE-L2 (for Chinese). We ran the multilingual system for all language pairs including to-English, as the large amount of non-English fine-tuning data made available in 2019 may benefit this setup too. We also release the predictions of BERT-BASE-L2, BERT-LARGE-L2, and MBERT for analysis.

5 Additional Improvements on English→German

For English→German, the organizers of WMT20 provide three different reference translations: two standard references and one additional paraphrased reference. Given this novel setup, we investigate how to combine our predictions. Moreover, we use a similar framework to ensemble the predictions of different metrics. In particular, we average the predictions of BLEURT, YISI-1 and YISI-2. All three metrics are different in their approaches. While BLEURT and YISI-1 are reference-based metrics, YISI-2 is reference-

free and calculates its score by comparing translations only to the source sentence. BLEURT is fine-tuned on previous human ratings, while YiSi-1 is based on the cosine similarity between BERT embeddings of the reference and the candidate.

In the remainder of this section, we report BLEURT results using the mBERT-WMT setup unless specified otherwise.[3]

5.1 Modifications to YiSi-1

Before combining BLEURT and YiSi, we perform a series of modifications to YiSi-1 and evaluate their impact on English→German.

Experimental Setup All experimental results are summarized in Table 5. We report both segment-level (DARR) and system-level (Kendall τ) correlations. To replicate the multi-reference setup of 2020, we compute correlations with the standard WMT references as well as the paraphrased reference from Freitag et al. (2020).

Improving YiSi's Predictions Our baseline is similar to the YiSi-1 submission from WMT 2019 (Lo, 2019): we run YiSi-1 with the public multilingual mBERT checkpoint. We then experiment with the underlying checkpoint. We continued pre-training mBERT on the in-domain German NewsCrawl dataset. The resulting model *+pre-train NewsCrawl layer 9* increases the correlation for both reference translations. We improve the correlation further on the paraphrased reference by using the 8th instead of the 9th layer.

Other experiments We tried pre-training BERT on forward translated sentences from German NewsCrawl, to adapt the word embeddings to MT outputs. We also trained a BERT model from scratch on the German NewsCrawl data. These experiments did not result in higher correlations with human ratings.

[3]We use a different checkpoint from the one described in Section 4. The model was trained for 880K steps instead of 1 million, and it uses a sequence length of 256 tokens instead of 128.

The second set of results is generated by using the paraphrased reference translations. YiSi-2 is reference free and only uses the source sentences.

5.2 Combining BLEURT, YiSi-1 and YiSi-2 on Multiple References

We describe our two submissions to WMT 2020, YiSi-COMB and ALL-COMB, which result from our efforts to use multiple references for automatic evaluation. YiSi-COMB is a multi-reference version of the YiSi score (Lo, 2019) aimed at achieving better system-level correlations. ALL-COMB leverages metrics from BLEURT, YiSi-1, and YiSi-2 on multiple references to achieve better segment-level correlation.

YiSi-COMB YiSi scores are F_1 scores of YiSi precision and YiSi recall. For the YiSi-COMB submission, we take the minimum of the YiSi recalls for the three different references as the multi-reference recall, and the maximum of the YiSi precision as the multi-reference precision. Using the same notations as in (Lo, 2019), the final score is the F_1 of the recall and precision computed with $\alpha = 0.7$ (see Figure 1). This submission aims to maximize the system-level correlation.

As shown in Table 5, YiSi-1 has the highest system-level correlation on paraphrased references. Given that we used $\alpha = 0.7$, YiSi scores are quite similar to YiSi recalls (when $\alpha = 1.0$, YiSi scores are equal to YiSi recalls). YiSi-1 scores for paraphrased references are usually much lower than those of standard references, therefore taking the minimum recall is oftentimes equivalent to taking the YiSi recall from the paraphrased references. Furthermore, we found that using the maximum precision, in combination with aggregating recalls, usually performs the best.

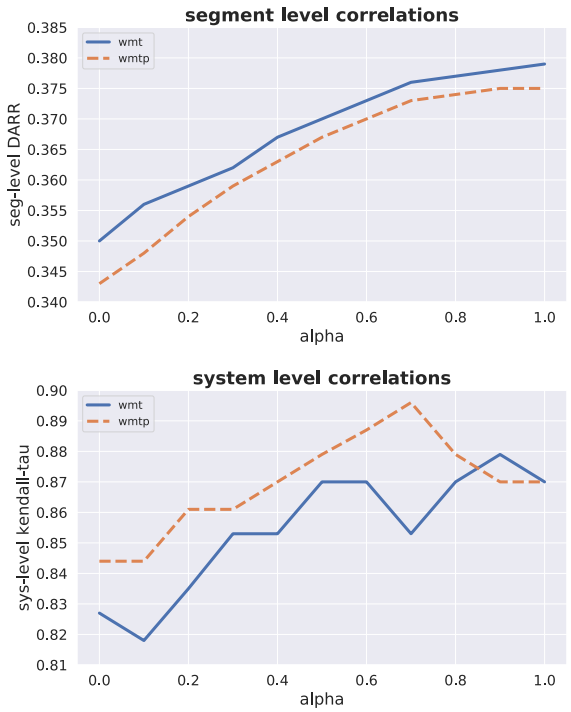

Figure 1: Correlations with respect to different α settings for Yisi-1. The system-level correlation is highest when $\alpha = 0.7$, which is the α we use for the submission.

ALL-COMB We combined the predictions of YISI-1 with those of BLEURT and YISI-2. YISI-2 usually performs worse than the reference-based metrics, but we found that incorporating its predictions can help. Having three different metrics (BLEURT, YISI-1, YISI-2) and three different reference translations, we take all seven predictions and average the scores for each segment. The combined prediction ALL-COMB outperforms every single metric at the segment level, though the system-level correlation drops in comparison to the best YISI-1 score on paraphrased references. This submission aims to maximize the segment-level correlation.

6 Summary

We submit the following systems to the WMT Metrics shared task:

- BLEURT as previously published, fine-tuned on the human ratings of the WMT Metrics shared task 2015 to 2019, to-English.
- A multi-lingual extensions of BLEURT based on a 20 languages variant of MBERT and BERT-CHINESE.
- Three baseline systems based on BERT-BASE, BERT-LARGE, and MBERT.
- Two combination methods for English to German that use YiSi and alternative references, YISI-COMB and ALL-COMB.

7 Acknowledgements

Thanks to Xavier Garcia and Ran Tian for advice and proof-reading.

Abstract

An important aspect of machine translation is its evaluation, which can be achieved through the use of a variety of metrics. To compare these metrics, the workshop on statistical machine translation annually evaluates metrics based on their correlation with human judgement. Over the years, methods for measuring correlation with humans have changed, but little research has been performed on what the optimal methods for acquiring human scores are and how human correlation can be measured. In this work, the methods for evaluating metrics at both system- and segment-level are analyzed in detail and their shortcomings are pointed out.

1 Introduction

In the past, machine translation (MT) metrics have been extensively studied and evaluated, at both system- and segment-level (Bojar et al., 2016, 2017; Ma et al., 2018, 2019). When performing system-level evaluation, the average score of a MT system is taken into account. Segment-level evaluation uses each sentence (segment) separately to compute correlation. The results of these metric evaluations are critical to the way MT metrics are perceived. In particular the correlation with human judgment is of great importance.

For this reason, an understanding for the workings of the evaluation method is required. Proposals to identify relevant system-level human scores have been discussed (Koehn, 2012; Sakaguchi et al., 2014), but no comprehensive analysis on this topic has been conducted. In particular, detailed studies on the segment-level evaluation are neglected, although it is an integral part of the metric evaluation.

Since the goal of a metric is to evaluate a translation as close as possible to a human's rating, it is important to clearly define the methods of determining human score and the methods of correlation measurement. This work aims to present an overview of the methods used in the evaluation, analyze their strengths and weaknesses, and propose solutions to some of the pitfalls of the methods.

2 Human Scores

To measure the correlation between the score of a metric and the score of a human, a method of determining human scores is required. Thus, a person has to judge the quality of a translated sentence. This is not a simple task, as different people may have different opinions about the exact quality of the translation. Another aspect to consider is that in order to calculate correlation, the score must be quantifiable in some way. Thus, the methods used to detect human judgment must use a sufficient number of human judges for them to be reproducible.

In the Workshop on Statistical Machine Translation (WMT), three different methods are used to determine the human score: direct assessment (DA) (Graham et al., 2017), relative ranking (RR) (Stanojevic et al., 2015) and, in recent years, relative ranking out of direct assessment (DARR) (Bojar et al., 2017).

2.1 Direct Assessment

The DA measures the quality of a translation on a scale from 0 to 100, based on the adequacy and fluency of the sentence. To obtain the score, the human judges are provided with a reference translation and the output of a single MT system, which makes the evaluation process monolingual. To ensure reproducibility, a large number of judges are needed – at least 15 (Ma et al., 2019). Additionally, scores are standardized (Graham et al., 2017) to eliminate individual distortions, such as judges who only provide high or low scores. Furthermore, a form of quality control is applied to filter out

Proceedings of the 5th Conference on Machine Translation (WMT), pages 928–933
Online, November 19–20, 2020.

judges who exhibit a high variance in comparison to their peers.

Overall, DA is one of the best ways to obtain human judgement. It provides a numerical score that can be easily used in common statistical methods, such as Spearman's ρ (Spearman, 1987) or Pearson's r (Pearson and Galton, 1895), at both the segment- and the system-level. However, to obtain statistically significant correlation measurements and ensure reproducibility, a high number of human scores are required. For the segment-level it is therefore infeasible to obtain DA scores. This leads to the need to use a completely different method for determining human judgements at the segment-level. Another possibility is to establish a relative ranking of the few obtained DA scores (DARR).

2.2 Relative Ranking

The RR produces, as the name implies, a ranking between multiple translations. In WMT, the judges are presented with five system outputs with the corresponding source and reference sentence, making the evaluation process bilingual. Each judge ranks the five sentences from the best to worst, taking equality (tie) into account. To simplify the evaluation, identical sentences from different systems are collapsed into one.

The resulting relative ranking of five tuples is not as straightforward to use for correlation calculation, since most correlation coefficients rely on absolute ranking information. One approach to obtaining a correlation is to use a variant of Kendall's τ (Kendall, 1938; Macháček and Bojar, 2014). This entails converting the scores produced by metrics into relative rankings. Naturally, this has the disadvantage that the fine granularity of the scores is lost. However, this method can be used for both segment- and system-level correlation calculations.

Another option used in WMT16 (Bojar et al., 2016) is to convert relative rankings to absolute rankings through TrueSkill (Herbrich et al., 2006; Sakaguchi et al., 2014). This method uses the relative rankings to estimate an absolute score for each system, which is then used to calculate the correlation (by Pearson's r or Spearman's ρ). The score of each system is represented by a Gaussian distribution, with the mean of the predicted score of the system and the variance of the confidence in that prediction. Due to the nature of the method, it can only be used for the system-level correlation calculation. This, in turn, makes it difficult to interpret the results since normally two different correlation calculation methods must be used for the different evaluation levels.

2.3 DARR

Due to the difficulty of obtaining enough DA scores for a statistically significant segment-level correlation calculation, Bojar et al. (2017) introduced the concept of obtaining a relative ranking from the DA used at the system-level and termed DARR. For this purpose, all possible sentence pairs, for which a DA score is available, are generated between all participating systems. These sentence pairs are then filtered to remove ties. The criterion used by Ma et al. (2019) is to remove sentence pairs, whose difference on the DA scale is less than 25. This should lead to the removal of all ties and produce an RR that scores the systems only as better or worse. However, this is not the case. Table 1 shows the RR of sentences with a sentence identifier (`SID`) on different language pairs (`LP`). The system that has achieved a better translation according to the DA score for these sentences is under the column `better`. In this case, the sentences generated by both systems are completely identical, as can be seen in Table 2, although they have been classified as different according to the DARR method. Such identical sentences occur across multiple language pairs in the WMT19 data set.

Another important aspect is that tie filtering is not applied to the metrics scores and therefore ties are possible for metrics. This makes the correlation calculation, especially for identical sentences, a difficult task. It is therefore of interest to determine how many identical sentences are present after filtering. For this reason, a brief analysis is carried out on the basis of the WMT19 data using six language pairs, which is shown in Table 3. There are no identical sentences for the language pairs Gujarati→English (`gu-en`) and Kazakh→English (`kk-en`). However, for all other language pairs, especially Chinese→English (`zh-en`), there are identical sentences. Note that these identical sentences are present after the tie filtering. Table 3 also shows the amount of ties produced by two metrics: YiSi-1 (Lo, 2019) and EED (Stanchev et al., 2019). It is clear that a significant amount of the ties for the two metrics come from identical sentences.

In addition, a considerable amount of data is eliminated. Figure 1 depicts the effect of varying the equivalence threshold, i.e. cases, in which the

LP	data	SID	better	worse
de-en	newstest2019	1200	uedin.6749	UCAM.6461

zh-en	31k	152	336	361
en-gu	11k	5	8	13
en-kk	18k	23	53	64
en-zh	19k	84	205	455

Table 3: Number of identical sentences vs. ties in the WMT19 corpus used for human correlation.

difference in DA scores is below the specified value, are considered as ties. Note that the threshold influences the amount of data used immensely. By having virtually no threshold (a threshold of 1) the average number of sentences is five times higher than when using a threshold of 50. The threshold of 25 used by WMT19 almost halves the amount of data used to acquire the correlation.

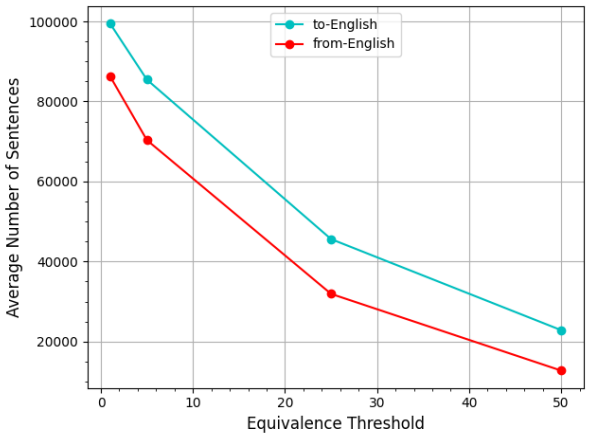

Figure 1: The average number of sentences over different language pairs (`to-English` and `from-English` directions) when excluding ties based on various equivalence thresholds.

Overall DARR provides a method for calculating the correlation at the segment-level in a scenario where there is not enough DA data. However, removing ties as part of the human component makes the evaluation unfair. This is aggravated by the fact that after DA-based tie filtering, not all ties are successfully removed. One possible solution, which remains to be tested, is to consider the ties of the human component carefully. This would at least equal the domain of metrics and human scores.

3 Measuring the Correlation

Obtaining human scores is only part of the correlation calculation. The other one is to use both human and metric scores to compute their similarity or correlation. The case, where both human and metric scores are represented by absolute values, is straightforward to compute using methods such as Pearson's r or Spearman's ρ. However, DA relies on a large amount of annotators that cannot always be guaranteed, especially at the segment-level. In the case where RR or DARR is used for human scores, this task is not that easy. For this reason, the focus here is on the case where a form of RR is used – typically for the segment-level correlation calculation.

As previously mentioned, WMT uses a form of Kendall's τ to obtain a correlation given the relative ranking. The coefficient definition in its most general form is shown in Equation (1)

$$\tau = \frac{|\text{concordant} - \text{discordant}|}{|\text{concordant} + \text{discordant}|}, \qquad (1)$$

where the concordant pairs denote cases in which there is agreement between the metric and the hu-

[1]Scripts and data from: http://ufallab.ms.mff.cuni.cz/~bojar/wmt19-metrics-task-package.tgz

man score, and the discordant pairs cases in which there is disagreement.

To formally define agreement and disagreement, a matrix can be used as described by Macháček and Bojar (2014). The various matrix formulations that have been used in WMT over the years are shown in Table 4. For metric scores to be interpretable in these matrices, a relative ranking must be constructed from the absolute scores for each participating metric. This is achieved by performing a pairwise comparison of the participating systems at the segment-level, taking into account ties. All three matrices treat matches and mismatches identically:

- discordant pairs are always cases where there are disagreements between the human and metric scores: $\{<, >\}$ or $\{>, <\}$,
- concordant pairs are always cases where the scores match: $\{<, <\}$ or $\{>, >\}$.

The only difference between the three methods is the treatment of ties.

Table 4a ignores the existence of ties. However, this is not desirable since ties are possible for metrics. Therefore, metrics are not evaluated on the same amount of sentences. This can be particularly detrimental to metrics that produce a large number of ties. For example, a metric with 99 ties and 1 concordant pair would achieve perfect correlation, while a metric without ties and 70 concordant and 30 discordant pairs would give a correlation of 0.4. The discrepancy in the results due to the data difference is evident.

On the other hand, incorporating ties while not considering human score ties can also lead to undesirable results. In Table 4c, which is used in WMT19, metric ties are considered as a discordant pair $\{<, =\}$ and $\{>, =\}$. Since ties are not defined (or included) in human scores, every tie produced by a metric results in a discordant pair. This in turn reduces its correlation. Thus, a "perfect" metric would never produce a tie between two sentences. This assumption does not reflect reality. In addition, the matrix is not symmetric since there are more possible discordant pairs than concordant ones. This means that a reasonable interpretation of the negative correlation is not possible. Therefore, metrics that have a negative correlation, such as TER (Snover et al., 2006), CHARACTER (Wang et al., 2016) and EED (Stanchev et al., 2019), must be mapped from an error (or edit) rate (E) to an accuracy score to ensure a relatively fair evaluation. This is not trivial, as there is no standard way to convert these metrics into the accuracy rate: neither $1 - E$ nor $-E$ is optimal.

A middle ground between the penalization and the ignoring of ties is the matrix in Table 4b. The ties are not penalized directly, but affect the overall correlation since they are part of the denominator:

$$\tau = \frac{|\text{concordant} - \text{discordant}|}{|\text{concordant} + \text{discordant} + \text{ties}|} \quad (2)$$

Since there is no hard penalization for metrics that produce more ties, such metrics are at a disadvantage. For example, a metric with 20 ties and 80 concordant pairs would achieve a correlation of $80/(80 + 20) = 0.8$, although all non-tie pairs achieve perfect correlation. On the other hand, a metric that overproduces ties, for example, with 80 ties and 20 concordant pairs, would have a correlation of $20/(20 + 80) = 0.2$. It can also be argued that measuring the correlation on metrics with a too high percentage of ties is not significant, since there are too few sentence pairs that are concordant or discordant.

One possible solution to the problem is shown in Table 5. The cases where there is clear agreement or disagreement between humans and metrics remain unchanged. In cases of tie disagreements, a soft penalization is added. This soft penalization is realized the same manner as in Table 4b using Equation (2). In the case where both the metric and human scores tie the two systems, a concordant pair (1) for accuracy-based metrics and a discordant pair (-1) for error rate-based metrics are given. This allows the process to be symmetrical and avoids the problem of having to map error rate to accuracy or vice versa. In addition, ties can now positively affect the correlation and all metrics are evaluated on the same amount of data. Naturally, this alteration of the evaluation method requires that ties be included in the RR. When using DARR, this can be achieved by considering all pairs, where the DA score difference is less than 25, and where the system translations are identical, as ties. A disadvantage of this method is that a distinction has to be made between metrics that aim for a strong negative correlation and metrics that aim for a strong positive correlation. Moreover, the exact range, where a tie is considered, is not necessarily clear.

		Metric		
		<	=	>
Human	<	1	X	-1
	=	X	X	X
	>	-1	X	1

(a) No tie penalization

		Metric		
		<	=	>
Human	<	1	0	-1
	=	X	X	X
	>	-1	0	1

(b) Soft tie penalization

		Metric		
		<	=	>
Human	<	1	-1	-1
	=	X	X	X
	>	-1	-1	1

(c) Hard tie penalization

Table 4: Kendall's τ evaluation matrices (Machácek and Bojar, 2014; Ma et al., 2019).

		<	=	>
Human	<	1	0	-1
	=	0	{1,-1}	0
	>	-1	0	1

Table 5: Integration of human ties in Kendall's τ.

4 Discussion

The MT metric evaluation is an area that needs further investigation. This work gives an overview of the methods used so far and highlights some of their shortcomings. The system-level assessment currently seems to be good, but the evaluation methods at the segment-level still need to be explored (in particular, if there is not enough DA data to directly calculate the correlation at the segment-level):

- It might not be a good idea to rule out tie cases: in theory, there are identical translations and translations of the same quality, and the metrics should be able to give them the same score; in practice, we have shown that excluding all tie cases eliminated a large proportion of the scores collected, which will have a significant impact on the final results. However, it is difficult to clearly define the tie cases for human evaluations, as in DA, on a scale from 0 to 100, different human annotators can give different scores for identical translations.

- The threshold for tie cases is not well defined. Further studies on the threshold value can be carried out. And also whether a threshold should be applied to the automatic metric scores. This study itself may not be a theoretically well-defined task, but some insight could be gained by examining the performance of various metrics under different thresholds.

- The used correlation coefficient is not symmetrical. Then the metrics with negative correlations have to be preprocessed before the evaluation, which can lead to inconsistencies. The proposed solution may also have potential problems as described, but it is worth doing further studies to define a better correlation coefficient.

In general, the task of creating a metric evaluation that is fair and reproducible for all metric types remains to be solved and deserves more attention and study.

Abstract

Copying mechanism has been commonly used in neural paraphrasing networks and other text generation tasks, in which some important words in the input sequence are preserved in the output sequence. Similarly, in machine translation, we notice that there are certain words or phrases appearing in all good translations of one source text, and these words tend to convey important semantic information. Therefore, in this work, we define words carrying important semantic meanings in sentences as *semantic core words*. Moreover, we propose an MT evaluation approach named *Semantically Weighted Sentence Similarity (SWSS)*. It leverages the power of UCCA to identify semantic core words, and then calculates sentence similarity scores on the overlap of semantic core words. Experimental results show that SWSS can consistently improve the performance of popular MT evaluation metrics which are based on lexical similarity.

1 Introduction

Machine Translation Evaluation (MTE) is to evaluate the quality of sentences produced by Machine Translation (MT) systems. Most automatic MT evaluation metrics compare the candidate sentences from MT systems with reference sentences from human translation to produce a similarity score, in contrast some other reference-less metrics directly compare candidate sentences and source sentences.

According to the observation of well-translated sentences, we find out that there are certain words or phrases appearing in all good translations of one source text. This phenomenon is consistent with the intuition of copying mechanism (Gu et al., 2016), which has been widely used in lots of text generation tasks. In the field of MT evaluation, Meteor++ (Guo et al., 2018) firstly proposes the concept of *copy knowledge* to define the words with copy property, and it further incorporates the copy knowledge into Meteor (Denkowski and Lavie, 2014) to improve its performance. Specifically, it attempts to find copy words of references and candidate sentences, and uses the overlap of these words to modify the calculation of precision and recall of Meteor. However, Meteor++ uses named entities as an alternative to copy knowledge in its experiments, resulting in a limited range of selected copy words and a slight improvement.

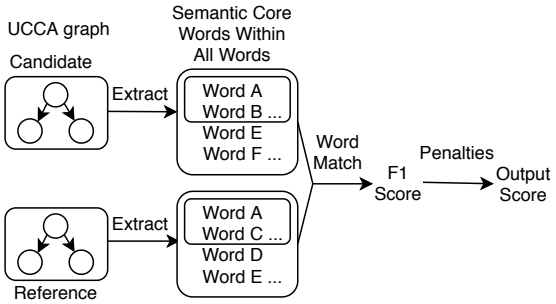

Figure 1: An illustration of the process of SWSS.

In this work, we argue that words undertaking important semantic meanings should be exactly expressed during the translation procedure, which we define as semantic core words. This concept is much more general and closer to linguistic intuition compared to the copy knowledge used in Meteor++. In order to apply semantic core words in the process of MT evaluation, we design a mechanism named *Semantically Weighted Sentence Similarity (SWSS)* illustrated in Figure 1. Firstly, SWSS extracts semantic core words according to the annotated semantic labels in Universal Conceptual Cognitive Annotation (UCCA) (Abend and Rappoport, 2013), a multi-layered semantic representation. UCCA is an appealing candidate for this mechanism as it includes a lot of fundamental semantic phenomena,

Proceedings of the 5th Conference on Machine Translation (WMT), pages 934–939
Online, November 19–20, 2020.

such as verbal, nominal and adjectival argument structures and their inter-relations. Also, semantic units in UCCA are anchored in the text, which simplifies the aligning procedure a lot. With the assumption that all high-quality translations should have the same semantic core words, SWSS then calculates precision and recall based on the overlap of semantic core words between sentence pairs and their corresponding F1 scores. Finally, we modify the F1 score according to the differences of two UCCA representations. For example, *Scenes* are involved in the penalties, which are essential nodes in UCCA indicating actions and states of the sentences. Our experimental results show that SWSS can be combined with other popular MT evaluation metrics to improve their performance significantly.

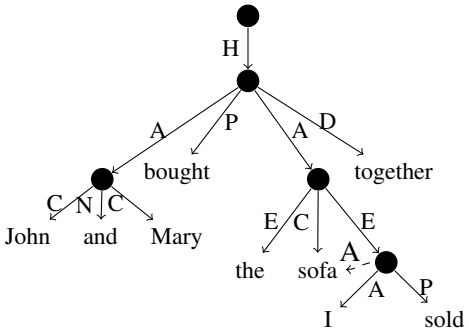

Figure 2: UCCA representation of sentence "John and Mary bought the sofa I sold together". Labels include *Parallel Scene (H)*, *Participant (A)*, *Process (P)*, *Adverbial (D)*, *Center (C)*, *Connector (N)*, *Elaborator (E)*. Dash line indicates a secondary semantic relation. There are two scenes in this sentence, the whole sentence and "I sold (sofa)".

2 Related Work

2.1 Machine Translation Evaluation

BLEU (Papineni et al., 2002) and Meteor are two most popular MT evaluation metrics. BLEU measures n-grams overlapping between the candidate sentences and reference sentences, while Meteor aligns words and phrases to calculate a modified weighted F-score. The two metrics are based on lexical similarity but somehow neglect semantic structure information of the sentences.

Efforts have been made to incorporate linguistic features and resources into MT evaluation. RED (Yu et al., 2014) makes use of dependency tree and MEANT (Lo et al., 2012) makes use of semantic parser. Categories such as part-of-speech (Avramidis et al., 2011) and named entity (Buck, 2012) also have their effects. In order to complement WordNet (Miller, 1998) and paraphrase table in Meteor, Meteor++2.0 (Guo and Hu, 2019) applies syntactic-level paraphrase knowledge.

2.2 Semantic Representation

Semantic representation focuses on how meaning is expressed in a sentence. Some semantic representation frameworks such as UNL (Uchida and Zhu, 2001) and AMR (Banarescu et al., 2013) use concept nodes to represent content words of sentence, and use directed edges with labels to indicate the semantic relation between nodes.

UCCA is a novel multi-layered semantic representation framework, which converts a sentence into a directed acyclic graph (DAG). Leaf nodes of UCCA graph correspond to words in the sentence, and a non-leaf node represents the combination of meanings of its child nodes. A parent node and a child node are connected by a directed edge which demonstrates the semantic role of the child node in the meaning of the parent node. Figure 2 is an example of UCCA representation.

Scene is an essential concept in UCCA. A scene describes some movement, action or a state in the sentence. Scene nodes in UCCA representation may be connected to the root node, or embedded in other scenes as arguments or modifiers. A scene node has a main relation, either a *Process* or a *State*, and may have some *Participants* or some *Adverbials*. These non-scene nodes may also have inner structure.

UCCA has been applied in many fields of Natural Language Processing. SAMSA (Sulem et al., 2018) is a Text Simplification evaluation metric that defines minimal center of UCCA representation and compares simplified text with the minimal centers of original sentences. It is also used in evaluation of faithfulness in Grammatical Error Correlation (Choshen and Abend, 2018) and human MT evaluation (Birch et al., 2016).

3 Proposed Method

3.1 Semantic Core Words

The most popular MT evaluation metrics such as BLEU and Meteor are based on lexical similarity. This kind of metrics cannot obtain insight into semantic structure of the whole sentence. Our proposed semantic core words are extracted from UCCA semantic structures and used to improve

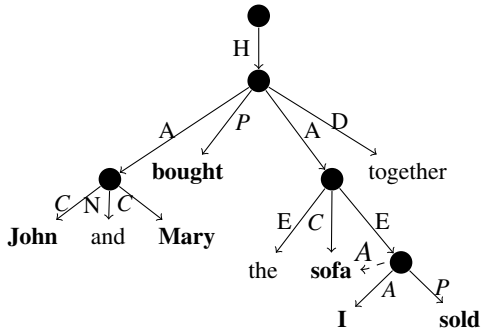

Figure 3: An example of semantic core words. The sentence is the same with Figure 2. All semantic core words are bold and the semantic labels of related edges are italic.

these lexical metrics as we expect them to play the role of copy words.

It is a linguistic intuition that some words carry more semantic information than other words in a sentence. For example, a modifier is usually less important than the word it modifies. In this paper, We define words that have important semantic information as semantic core words. According to their semantic importance, they are expected to be accurately translated during translation. Therefore, we assume that in all good translation results of a specific sentence, the set of semantic core words should be the same, behaving like copy words.

We extract semantic core words of a sentence from its UCCA semantic representation. The lowest semantic role label in the representation for each word is considered, which also indicates the most basic semantic role of a word. A word whose lowest semantic role is *Process*, *State*, *Participant* or *Center* is identified as semantic core words. Figure 3 marks semantic core words of the example sentence. The result is consistent with our intuition of which word has important meaning in this sentence.

3.2 Word Matching

After semantic core words are extracted from UCCA representations, a word matching algorithm should be applied in order to match all words between the two sentences. In this paper, we use a stemming algorithm. Two words are matched if they have the same stem.

We count how many semantic core words in a candidate sentence can be matched to any semantic core words in the reference sentence, and compute the proportion as precision. Similarly, we calculate the matched proportion of semantic core words in reference sentence as recall. In our word matching algorithm, it is possible that a word in a sentence is matched to multiple words in the other sentence because they all have the same word stem. However, just like what is conducted in BLEU, a word cannot be contained in multiple matching pairs. The precision and recall are then used to calculate F1 score. We use F1 score here to ensure that SWSS is symmetrical and can be directly used as a sentence similarity metric.

$$
\begin{aligned}
P &= \frac{\sum_i w(h_i) \cdot m(h_i)}{\sum_i w(h_i)} \\
R &= \frac{\sum_i w(r_i) \cdot m(r_i)}{\sum_i w(r_i)} \\
F_1 &= \frac{2P \cdot R}{P + R}
\end{aligned}
\tag{1}
$$

Take the calculation of precision as an example. h_i means each semantic core word in the candidate sentence, and $w(h_i)$ is its weight. Though in this paper the weight is fixed to 1, it can be fine-tuned or trained in future work. If h_i can be matched to any semantic core word in the reference sentence, $m(h_i)$ is set to 1, otherwise $m(h_i)$ is set to 0. However, $m(h_i)$ can also be different values related to matching type like the operation in Meteor, which might be conducted in future work.

A fact is that the UCCA parser we used might occasionally produce an analysis result in which there are no semantic core words in a sentence, which causes division by zero during calculation. In these cases a fixed score ω is used as an alternative.

3.3 Penalty and Combination

According to the intuition that good translation results of a specific sentence should have similar semantic structures, we introduce three penalties concerning statistical differences of two UCCA representations.

- The ratio between counts of scenes of two representations. Let S_1, S_2 be the counts of scenes, the penalty P_S is $1 - \min(S_1, S_2)/\max(S_1, S_2)$.
- The ratio between counts of nodes of two representations. Let N_1, N_2 be the counts of nodes, the penalty P_N is $1 - \min(N_1, N_2)/\max(N_1, N_2)$.
- The ratio between counts of edges towards critical semantic roles of two representations,

Table 1: Segment-level Pearson correlation comparison between base model and the combination of SWSS and base model. The smoothing parameter X of Meteor++ is set to 8, which is used on WMT15 dataset in its paper.

which are *Process*, *State* and *Participant*. This count is the sum of count of scenes and count of all arguments in the sentence. Let E_1, E_2 be the counts of these edges, the penalty P_E is $1 - \min(E_1, E_2)/\max(E_1, E_2)$.

The three penalties are set to 0 if the counts are equal and their upper bound is 1. Additionally, we also notice that the average word count of a sentence pair can act as another penalty Len. Applying the four penalties, the final score is calculated by the equation below. All parameters here are tunable.

$$Score = F_1 \cdot \exp(-\alpha_1 \cdot P_S - \alpha_2 \cdot P_N - \alpha_3 \cdot P_E - \alpha_4 \cdot Len) \quad (2)$$

The SWSS score is calculated independently. Therefore, as a semantic structure-based component, it can be further combined with other MT evaluation metrics to obtain a more accurate evaluation metric. For example, we can obtain a simple weighted model of SWSS and Meteor by tuning the weight β below.

$$SWSS \star Meteor = Meteor + \beta \cdot Score \quad (3)$$

4 Experiments

4.1 Data

SWSS is evaluated on WMT15 (Stanojević et al., 2015) and WMT16 metric task (Bojar et al., 2016) evaluation sets and is tuned on WMT17 metric task (Bojar et al., 2017) evaluation set. The datasets are composed of pairs of system output sentences and reference sentences, and also corresponding human evaluation scores for the output sentences.

α_1	0.2	α_4	0.01
α_2	1	β	0.2
α_3	0.5	ω	0.5

Table 2: Parameters of SWSS in experiments.

The evaluation set of WMT15 has 4 language pairs and each has 500 sentence pairs. WMT16 dataset has 6 language pairs and WMT17 dataset has 7 language pairs, and each has 560 sentence pairs. Performance of a metric is evaluated by Pearson correlation between scores provided by the metric and the human evaluation scores.

4.2 Settings

The parameters of SWSS are tuned on the dataset from WMT17 metric task and are listed in Table 2. We use SpaCy library[1] for word tokenization. Word stems are extracted with Porter stemming algorithm (Porter et al., 1980). UCCA representations are parsed with the pre-trained model of TUPA (Hershcovich et al., 2017).

4.3 Results

SWSS is combined with base models including BLEU, Meteor and Meteor++. Table 1 shows that the combined models lead to significant improvement of Pearson correlation compared to the base models. It can be inferred that adding SWSS as a component to MT evaluation metrics based on lexical similarity can improve their performance. The results also indicates that SWSS performs better than Meteor++, as SWSS regards all semantic core words as copy words while Meteor++ uses only named entities in its experiments. Semantic core

Table 3: Results of ablation experiments. "+UCCA" is the complete SWSS model combined with Meteor, "-repr" means the penalties based on UCCA representation (P_S, P_N, P_E) are removed, "-len" means the length penalty is removed, and "None" contains only Meteor without SWSS.

words is clearly a good and large-scale representation of copy words, according to the results.

We also conduct ablation study to figure out whether the penalties we have introduced are redundant or not. The base model is the combination of SWSS and Meteor. If we remove the representation penalties or the length penalty from the base model, it can be found out from Table 3 that the modified models have lower correlation than the complete model. The result with $p < 0.05$ proves that these penalties have a positive effect on the mechanism.

5 Conclusion

In this paper, we propose Semantically Weighted Sentence Similarity (SWSS), which leverages the power of UCCA to identify semantic core words, and then calculates a similarity score for machine translation evaluation. Inspired by copying mechanism used in sequence generation tasks, we argue that semantic core words, which carry important meaning in the sentence, should exist in all good translations. Additionally, SWSS also uses penalties based on the differences between UCCA structures and sentence lengths, including the concept of Scene in UCCA, in order to make the output scores more accurate. Experimental results show that SWSS can produce a higher correlation in MT evaluation when combined with lexical MT evaluation metrics such as BLEU and Meteor.

Abstract

This paper illustrates Huawei's submission to the WMT20 low-resource parallel corpus filtering shared task. Our approach focuses on developing a proxy task learner on top of a transformer-based multilingual pre-trained language model to boost the filtering capability for noisy parallel corpora. Such a supervised task also helps us to iterate much more quickly than using an existing neural machine translation system to perform the same task. After performing empirical analyses of the finetuning task, we benchmark our approach by comparing the results with past years' state-of-the-art records. This paper wraps up with a discussion of limitations and future work. The scripts for this study will be made publicly available. [1]

1 Introduction

Crawling web has been regarded as a *de facto* approach to produce bitexts, yet the crawled texts are under-qualified often in some aspects to train a proper machine translation system. Under-qualified bitexts present misalignments, no alignments, wrong language pairs, sentences mostly composed of numbers and mathematical formulas, etc. Parallel corpus filtering in this manner holds a critical research area to improve the performance of machine translation systems. WMT organizes a shared task for parallel corpus filtering since 2018 intending to filter our noisy bitexts to this end. The challenge targets low-resource language pairs since 2019.

Many existing filtering methods require multiple layers of elimination by implementing manually engineered features such as length filtering, language identification, normalizing, etc. These hand-picked features work well for a language pair but don't generalize well to another language pair or domain and often bring algorithmic complexity to the overall system.

The LASER (Artetxe and Schwenk, 2019) model achieved state-of-the-art (SOTA) records at the WMT19 shared task on low-resource parallel corpus filtering (Chaudhary et al., 2019). The sentence representation model implemented in LASER provides a means for measuring the similarity between a source and a target sentence. As stated in the future work at Artetxe and Schwenk (2019), there is still space to improve. Utilizing a self-attention mechanism remains future work as the LASER was not built upon the latest transformer architecture (Vaswani et al., 2017). We are also interested in designing a filtering tool that can be efficiently applied to a wide range of language pairs. Pre-trained multilingual language models, such as BERT (Devlin et al., 2018) and RoBERTa (Liu et al., 2019), are exploited to this end.

We make two contributions to the field in this manner. The first contribution is a proposal of approaching the filtering problem as a discrimination task that can be trained with a proxy task and synthetic training data generation (see in Section 3.1). The other contribution is the empirical knowledge learned from an analysis of the finetuning pre-trained multilingual language models on cross-lingual discrimination tasks.

2 Related Work

In the WMT18 shared task, participants mostly used similar techniques in components as prefiltering, scoring the sentence pairs, and using a classifier for feature functions. Teams applied prefiltering rules to eliminate noisy data, including:

- short or lengthy sentences;
- sentence pairs with few words and unbalanced token lengths;

*Corresponding author

Proceedings of the 5th Conference on Machine Translation (WMT), pages 940–946
Online, November 19–20, 2020.

- sentence pairs with unmatched names, numbers, web addresses, etc.;

- sentences where a language identifier fails to identify a source or target language type.

Scoring functions were mostly used to correlate qualified texts. Participants also used sentence embeddings (Bouamor and Sajjad, 2018; Axelrod et al., 2011; Artetxe and Schwenk, 2019) altogether with a similarity function to detect the similarity of pairs. The WMT19 shared task focused on low-resource languages, namely Nepali-English and Sinhala-English. Participants mostly applied basic filtering techniques similar to those used in 2018. Chaudhary et al. (2019) used sentence embeddings that were trained on parallel sentence pairs. Another approach was to train a machine translation system on the clean data and then used it to translate the non-English side to make a comparison. Several metrics were used to match sentence pairs such as METEOR, Levenshtein distance, and BLEU.

We found that our work relates to the submission from Bernier-Colborne and Lo (2019). However, their submission was unable to show the effectiveness of the proposed method due to potential issues in the pretraining process. Besides the parallel corpus filtering task, we come across several works utilizing a similar approach. In Yang et al. (2019), BERT rescoring method is more effective at bitext mining than heuristic scoring methods, i.e., marginal cosine distance. In Grégoire and Langlais (2018), a similar negative random sampling technique has been used for generating synthetic bad pairs. Also, attempts to create harder negative pairs were proven effective in bitext mining (Guo et al., 2018).

3 Methodology

Transformer models are currently state-of-the-art systems on most NLP classification and regression tasks. With the emergence of multilingual pretrained models, their cross-lingual capabilities can be exploited with little effort.

3.1 Proxy Task

To treat this problem as a supervised one, we design a proxy learner to model this task. The correctly aligned pairs can be regarded as positive samples in a simple sense for binary classification.

Most of the noise in the corpus originate from ill-aligned sentence pairs. The intuitive idea is to treat the misalignments as synthetic negative samples for our proxy task learner.

Taking random samples of the target sentences for all source sentences was the easiest way to create negative samples. But this results in an easily-classifiable training data which offers little assistance to the low-resource bitext filtering task. We need to create more valuable training data, which is referred to as harder examples.

3.1.1 Generating Harder Examples

Instead of training transformers with easily-discernible random negative samples, we need to create harder examples to confuse the model to boost its performance on the filtering task. We try the following ways to generate harder examples:

Neighborhood Awareness The neighbor sentences in the corpus have a higher chance of sharing common semantics and topics than those randomly extracted from corpus-wide. Alignment slips are most likely to occur in this context. This concept of neighborhood awareness inspires us to generate harder training data. For every positive pair, we create two negative pairs by pairing adjacent sentences of that target sentence with the source sentence. Incorporating this simple strategy may help to boost filtering performance.

Fuzzy String Matching Sampling Instead of randomly sampling negative examples from bitexts, we develop a new sampling strategy inspired by KNN (the k-nearest neighbors algorithm). To create harder examples for finetuning, we sampled lexically similar but semantically different sentences using a fuzzy string search method. [2] For each one of the source sentences (S), we perform a fuzzy search and identify the N similar sentence respecting to the fuzzy string score (F). We set a limit (L) on the F and ignore sentences with similarities over this limit (L) to avoid duplicated or highly related candidates. Then we pair the corresponded target sentences of those N similar sentences with the source sentences to create N negative pairs. We apply a setting with an L value of 60 (in a 100 scale) and N values of 2 and 3 to generate the validation and training data.

Model Architecture	Siamese	Finetuning
Bert-base-Multi-cased	0.62	0.69
Xlm-Roberta-Base	0.84	0.86
Xlm-Roberta-Large	0.88	0.92

Table 1: Model performances on proxy task as accuracy in F1 scores.

3.1.2 Architecture

We explore two candidate architecture in this study, one of which is a Siamese network (Reimers and Gurevych, 2019). The other model is a pre-trained transformer with a binary classification learner to differentiate ok-aligned sentence pairs with their negative counterparts. A comparison between the performance of architecture can be seen in the Table 1.

Sentence Transformers Reimers and Gurevych (2019) adopt a Siamese architecture, which allows us to feed sentence pairs separately to a transformer network like BERT. Each sentence pairs are encoded into fixed-size embeddings connected to a classifier network. Embeddings can be compared using a cosine similarity function at the inference stage. We reach on par performance to the LASER in the WMT19 parallel corpus filtering task (Table 3).

Transformer Finetuning with Pair Classification BERT is a language model introduced by Devlin et al. (2018). A pre-trained BERT model can be finetuned by adding an extra output layer to address many NLP tasks. One of BERT's derivatives is RoBERTa (Liu et al., 2019), and it is essentially very similar to its successor in structure. The authors of RoBERTa discarded the next sentence prediction (NSP) task and altered the mask language modeling task.

We compare multilingual variations of BERT and RoBERTa, which contains both Khmer (km) and Pashto (ps) monolingual data in the pretraining. The multilingual version of the RoBERTa, aka XLM-R (Conneau et al., 2019), performs far superior as it leverages more data in training (Table 1).

3.1.3 Amount of Parallel Data

To observe the effect of the amount of the available parallel corpus on this proxy learner's performance, we try two different data regimes. The orange line in Figure 1 represents a very low resource setting, and we subsampled 2k parallel pairs to mimic that. The blue line represents a 10k subsampled version of the training data. As can be seen from Figure 1, the more we increase the number of parallel sentences used in training the proxy task, the more performance we observe for the proxy task. Other than that, a system using almost as little as 2k parallel sentence pair is enough to beat the benchmark results. The proposed approach is promising for other low-resource domains and applications.

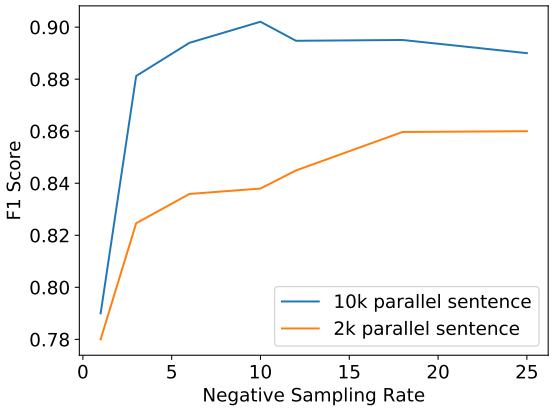

Figure 1: Proxy task validation performance in the face of changing volumes of training data (Pashto - English).

3.1.4 Negative Sampling Ratio

The amount of negative data that can be used in training is analyzed in the prior works (Section 2). Into our observations from Figure 1 and Figure 2, using larger negative ratios leads to better performances. However, it is better to keep the positive/negative ratio to $1:10$ for our datasets with a presence of more parallel data.

We oversample the positive pairs in the finetuning step to balance the positive-negative ratio. But it didn't make a noticeable change in proxy task performance or filtering performance. The immunity of the pre-trained transformer models to the class-imbalance up to 20x is very surprising.

3.1.5 Learning Rate

To prevent the catastrophic forgetting problem in the transformers, we apply a very small ($2e^{-6}$) learning rate with the inverse root scheduler and a warmup step of $1,000$. We also try other learning rate schedulers like cyclic learning rate scheduler (CLR) from (Lee et al., 2020) but couldn't observe any benefit for this task. We suspect CLR may not

[2]https://github.com/seatgeek/fuzzywuzzy

apply to a finetuning process with a small epoch number (i.e., 2 epochs in this study).

3.1.6 Finetuning and Scoring

We add a classification layer on top of XLM-R having $2,048$ hidden units with RELU activations and dropout. On single Nvidia V100 GPU, we finetune our models for 2 epochs without any early stopping. It takes about 6 hours to finetune on the generated datasets. The scoring step is just getting the probability of that pair being positive. Scoring a sentence pair takes $5ms$ on average.

3.2 Rescoring

Bidirectional Scoring Similar to the bidirectional scoring in Chaudhary et al. (2019), we reverse source and target sentences and train two different networks, which produce two different scores (SRC-TRG and TRG-SRC) for a pair. We then combine these two scores under (min, mean, max) strategies. In the "min" strategy, we aim to filter false-positive pairs by keeping the lowest score from the (SRC-TRG and TRG-SRC) for each pair. In "max" strategy, we use the highest score for each pair. And in the "mean" strategy, an average of the scores are applied. We observe that filtering on the "max" score can turn some of the false-negative sentences into true-positives, which increases NMT performance (Table 2).

Strategy	BLEU
SRC-TRG	12.97
TRG-SRC	12.65
Mean	12.42
Min	12.93
Max	13.17

Table 2: NMT results of systems trained after filtering based on different bidirectional scoring strategies (Pashto - English)

Ensembling We ensemble our top 3 trained transformer models under (min, max, mean) strategies and observe a minor improvement on the Pashto-English (ps-en) dataset. On the Khmer-English (km-en) dataset, there is no improvement (Table 3).

3.3 Heuristic Filters

Heuristic filters like overlap filters, length ratio, min-max length, and language identification are applied. For the Pashto-English setup, this step is not beneficial to the overall performance. For the Khmer-English setup, we observe a minor gain (Table 3). It appears that our scoring method can learn heuristic filtering on the fly without reliant on hard-coded heuristic filters.

4 Results

There is a relationship between F1 scores of the proxy task and the final NMT system performance (Figures 1-2). Improvements of the final NMT in the proxy task peaks along with the negative sampling rate and decreases potentially due to overfitting. By looking at the same ratio presented in Figures 1-2, we can conclude a correlation between the performance of the proxy task and that for the filtering task, showcasing the proposed approach's effectiveness.

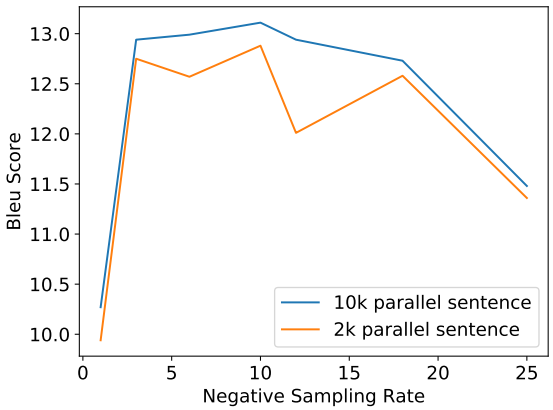

Figure 2: MBART performance of the filtering model (Pashto - English).

WMT20 Here we have presented our NMT performances of the submitted filtering systems in Table 3. Note that we measure all of the development cycles and improvements with the MBART finetuning (Liu et al., 2020). We do not replicate every experiment with training from scratch regime due to resource constraints. As shown in Table 3, our method outperforms the LASER baseline without needing any prefiltering rules and costly marginal KNN scoring method in solving the hubness problem for both language settings.

4.1 Older Tasks

To find how our method generalizes across different filtering scenarios, we test it for the past generations of this shared task.

WMT18 We use the same neural machine translation system defined by the organizers. Our NMT

Method	Pashto-English		Khmer-English	
	Scratch	MBART*	Scratch	MBART*
Baseline(LASER)	9.6	12.2	7.1	10.4
Sentence Transformers	9.7	12.5	7.5	10.6
XML-R finetuning	10.1	12.6	7.7	10.8
+Neighbourhood Awareness	-	12.9	-	-
+Fuzzy String Matching	-	13.0	-	-
+Bidirectional Scoring	-	13.2	-	11.5
+Ensemble Scoring	**10.9**	**13.3**	-	11.5
+Heuristic Filters (3.3)	10.7	13.2	**8.7**	**11.7**

Table 3: NMT scores (BLEU) of the models that trained on a corpus filtered by the specified methods on WMT20 test sets. The bold fonts indicate the SOTA results. * indicates finetuning of the pretrained MBART model which is provided by the organizers.

model using the submission by Junczys-Dowmunt (2018) couldn't reach the reported scores (can be observed in Table 4 for the $10M$ subsampled set). Although our method couldn't match the SOTA results under these settings, it achieves a reasonable score. Note that we only used 10% of the available clean parallel data to accomplish this result. Also, instead of finetuning a multilingual pre-trained model, bilingual models can be tried to avoid the curse of multilinguality (Conneau et al., 2019).

WMT19 Our NMT model using the submission by Chaudhary et al. (2019) couldn't reach the reported scores, as shown in Table 4 for the Nepalese-English (ne-en) set. The mismatches mentioned above with WMT18 and WMT19 are possibly due to a result of using multiple GPUs with distributed optimizers like stated in Koehn et al. (2019). In the low-resource setting, our method can surpass the SOTA results (Table 4).

Task	SOTA	OURS
WMT18 (de-en)	***27.9 (28.62)**	27.53
WMT19 (ne-en)	*6.9 (7.1)	**7.5**

Table 4: WMT18 and WMT19 filtering tasks test results. Note that numbers with "*" represent the submitted score performance under our NMT setup. Those in parenthesis are the reported scores.

5 Conclusions and Future Work

We illustrate our submission to the WMT20 low-resource parallel corpus filtering task. By developing a proxy task learner on top of a transform-based pre-trained language model XLM-R, We are able to improve the filtering capability for noisy data, achieving SOTA results.

The parallel corpus filtering task is recall-oriented. Therefore our model may not be suitable for high-precision jobs. The model has limitations in dealing with short sentences. It can be improved by finetuning on dictionaries or phase-based bitexts. The model performs better in low-resource and high-recall settings.

In our experiments depicted in the subsection 3.1.6, we observe low performances several times. It may appear the model is suffering from the random seeds caused fragility mentioned in Risch and Krestel (2020). A close look ascribes these abnormal results to the randomness in the sampling strategy. We leave this issue to future work.

Different kinds of synthetic noise generation techniques can be adapted to increase the robustness and accuracy of the model. For example in the filtered data we observed several false-positive cases which contains mis-translated numbers:

en reference:

"3) Sonar coverage: 45K at 200KHz"

ps to en translation:

"4) Sonar coverage: 90 at 125KHz"

Training an NMT model on this type of data hurts the translation performance. But this kind of noise can be fixed by altering the numerical values in the clean training data to sample negative pairs for our proxy task. Moreover, all the other synthetically generatable errors like a typo error, one to many alignment errors, etc. can be incorporated into the training data. But its not viable to model those kinds of errors independent from

the language or domain with the naive assumptions and inventing heuristic rules. We believe further researches should focus on domain invariant noise generation techniques.

Acknowledgments

We would like to show our gratitude to colleagues from HTRDC AIE and AARC, Huawei for their support during this work.

Abstract

This paper presents the description of our submission to WMT20 sentence filtering task. We combine scores from custom LASER built for each source language, a classifier built to distinguish positive and negative pairs and the original scores provided with the task. For the mBART setup, provided by the organizers, our method shows 7% and 5% relative improvement, over the baseline, in sacreBLEU score on the test set for Pashto and Khmer respectively.

1 Introduction

Neural machine translation (NMT) brings significant gains to the field of machine translation. However, it is known to be very sensitive to the quality of parallel data (Khayrallah and Koehn, 2018). This becomes a serious problem when using large but very noisy corpora for training. There is a lot of work on filtering noisy parallel data. For example, the work in (Junczys-Dowmunt, 2018) provides excellent results for large corpora. Low resource languages are even more challenging and the results in (Chaudhary et al., 2019) using multilingual embeddings are very encouraging.

This paper describes the system submitted to the WMT20 Shared Task on Parallel Corpus Filtering for Low Resource Conditions. Due to time limitation our submission covers only sentence pair filtering. However, some of the proposed techniques could be used for sentence alignment and filtering. The task focuses on the Pashto-English and Khmer-English language pairs. It is required that the participants calculate scores to sort very noisy parallel sentence pairs provided for each language. The top scoring pairs leading to 5M tokens on the English side are then used to train machine translation for each language pair. The organizers also provide LASER-based scores as a baseline according to the method in (Chaudhary et al., 2019), with possibly some modifications. We describe our general system architecture followed by development experiments to evaluate the merit of different methods and finally report the performance of our best setup per language, using the fairseq recipe provided for the task for both full training (from scratch), and finetuning (mBART) settings. mBART (Liu et al., 2020) is a recently proposed pretraining method. Models initialized using mBART for both language pairs are provided with the task.

Our proposed approach combine the scores provided by the organizers with the following two scores:

- Margin distance calculated based on custom LASER built for each language using parallel data and a large amount of forward translated mono data provided by the organizers.
- Cosine distance between the embeddings generated by a classifier taking the pretrained LASER as input and trained to distinguish parallel and non-parallel sentence pairs using parallel data provided in the task.

More details on the approach are provided in Section 2. For the mBART setup our method shows 7% and 5% relative improvement in sacreBLEU score on the test set for Pashto and Khmer respectively.

2 System Architecture

In this section we describe the overall system architecture. We start by presenting language-based preprocessing in Section 2.1.The scores provided by the organizers use pretrained LASER (Artetxe and Schwenk, 2019b) and margin distance (Artetxe and Schwenk, 2019a; Johnson et al., 2017). Actually their method obtained state-of-the-art results in WMT19 low resource filtering task for Sinhala,

Proceedings of the 5th Conference on Machine Translation (WMT), pages 947–951
Online, November 19–20, 2020.

Nepali and Hindi and hence is a very strong baseline. Therefore, we opt to construct sentence embeddings using two different methods, namely custom LASER and classifier-based embeddings, to complement the baseline pretrained LASER. Each embedding method is then used to generate a score for each sentence pair and all the scores are combined to form the final score. In the rest of this section, we will describe custom LASER in Section 2.2 followed by classifier-based embeddings in Section 2.3 and finally we outline score combination in Section 2.4.

2.1 Preprocessing

We first preprocess the data using language identification on the source side. The results reported in this paper use the BLING (BLING, 2020) tool from Microsoft but preliminary experiments indicate similar performance using python langid or fasttext (Bojanowski et al., 2017). One interesting feature of BLING is that it returns the percentages of different language constituents of a sentence. In the current implementation we keep sentences that have a language identification score of the source language of 80% or higher. All sentences that do not satisfy the language identification threshold are assigned a very low score and hence are not selected in the final candidate pairs. We will report results without using language identification in the experiments. We generally found it helps a lot for Khmer and actually hurts a bit for Pashto. We expect this is due to the larger Khmer size. Table 1 shows the original number of sentences and those filtered at 80% threshold for Pashto and Khmer.

Language	Original	Filtered (kept)
Ps	1,022,883	615,451 (60.17%)
Km	4,169,574	2,714,664 (65.11%)

Table 1: Number of sentences before and after language filtering

2.2 Custom LASER

Pretrained LASER (Artetxe and Schwenk, 2019b) has 93 languages. Some of these languages are under-represented and others, like Pashto, are completely missing. While similar languages tend to help each other it is clearly beneficial to have a custom LASER trained for the languages of interest. In WMT19 results (Chaudhary et al., 2019), custom LASER trained on a combination of Hindi, Sinhala and Nepali outperformed the pretrained LASER for the filtering task. Here, we build two separate models for Pashto and Khmer. Since both languages have very different origins we thought it is not beneficial to build a combined model but we haven't verified this experimentally. We use the LASERtrain package (Esplà and Sánchez-Martínez, 2019) to train the custom LASER. This package follows the LASER training as given in (Artetxe and Schwenk, 2019b) and provides experiments on BUCC'18 with good results. It is also possible to fine-tune the pretrained LASER using the languages of interest. We will explore this in future work.

Participants in WMT20 are limited to data provided by the organizers. The supplied parallel data for both languages is of rather limited size and is dominated by domain specific data as software localization and religious text and hence we use the provided monolingual text to augment the training data. For each language this is done as follows. We start with the provided sentence scores and filter 5M English tokens as suggested in the task. We use the resulting parallel data to train an mBART initialized MT system. The sacreBLEU scores on the development test set from the organizers and our internal run are shown in Table 2.

Language-pair	Organizers	Internal
Ps-En	12.2	11.6
Km-En	10.6	10.4

Table 2: SacreBLEU for mBART on development test set as provided by the organizers and for internal run.

In addition to the noisy parallel sentences, the organizers provide additional parallel data and monolingual data for both languages. The parallel data comes mainly from OPUS and consists of 290K and 123K pairs for Khmer and Pashto respectively. The monolingual data for Khmer has around 13M sentences while that of Pashto has around 6M sentences. For more information about the sources of these data we refer the reader to (EMNLP, 2020). The resulting internal system is used to forward translate various amounts of monolingual data from the source language into English. We found in preliminary experiments that using around 3M monolingual sentences gives good performance (more

on the evaluation below). These sentences are randomly selected from the monoingual data. The synthetic pairs for Pashto-English and Khmer-English are used to augment the provided clean parallel data to train the custom LASER for each language. The reason we build unidirectional custom LASER is that most of our data is synthetic and the performance of the translation in the opposite direction English-Pashto(Khmer) is expected to be quite poor. In addition, English is very well represented in the pretrained LASER.

It is good to have a way to evaluate the quality of the built custom LASER. Building machine translation (MT) every time is very costly. To this end, we use a BUCC-like setup to evaluate the quality of the custom embeddings. We use the development set for each language pair. For each sentence on the source side we use the corresponding embedding to find the nearest neighbor, based on cosine distance, on the target side and calculate the top-1 accuracy. We do the same in the other direction (target to source) and average both numbers.

$$\text{BUCC}(S) = \frac{1}{2|S|}\left(\sum_i \mathbb{I}\left(\arg\max_j S_{i,j} = i\right) + \sum_j \mathbb{I}\left(\arg\max_i S_{i,j} = j\right)\right) \quad (1)$$

where S is the matrix of pairwise similarity scores for pairs in the source-target development set. Accuracies using pretrained and custom LASER for Pashto and Khmer are shown in Table 3.

Language-pair	Pretrained	Custom
Ps-En	9.56%	31.97%
Km-En	1.04%	39.50%

Table 3: BUCC-like accuracy scores on devtest set of the filtration task

Once the custom LASER of a language is trained it is used to calculate the score of a sentence pair using the margin distance as shown in Equation 2. The margin is implemented efficiently using (Johnson et al., 2017).

$$\begin{aligned}\text{score}(x, y) = &\text{margin}(\cos(x, y), \\ &0.5\,(\text{mean}\,\{\cos(z, x) \mid z \in \text{NN}_k(x)\} \\ &+ \text{mean}\,\{\cos(z, y) \mid z \in \text{NN}_k(y)\}))\end{aligned} \quad (2)$$

2.3 Classifier-Based Scores

In addition to custom LASER presented in the previous section we use scores provided from a classifier trained to distinguish parallel and non-parallel sentence pairs. It takes pretrained LASER embeddings of a sentence pair u and v and transforms them using a fully-connected layer with ReLU nonlinearity. Similar to (Reimers and Gurevych, 2019) it inputs the concatenation $[u_{tr}; v_{tr}; |u_{tr} - v_{tr}|]$, where u_{tr} and v_{tr} are the outputs of the fully connected layer, to a softmax classifier with two outputs representing the positive and negative pairs. The network is trained using the cross-entropy criterion. During testing, LASER embeddings of a sentence pair are passed through the fully connected layer and their cosine distance is calculated as the required score. The rationale is that the transformed embeddings provide better representation to separate positive and negative pairs compared to pretrained LASER.

For each language, the classifier is trained on the positive pairs provided by the organizers. Following (Zhang et al., 2020) for each sentence the negative pair is selected at random from the following:

- Select a sentence from its adjacent sentences within a window size of k (where k = 2 in our experiments).
- Truncate 30-70% words of the sentence.
- Swap the order of 30-70% of the words of the sentence.

After forming the positive and negative data around 500 example pairs, per language, are kept as validation set. The classification accuracy, on the validation set, for Pashto is 97% while that of Khmer is 98.5%.

2.4 Score Combination

Based on the previous sections each input sentence pair x, y has three scores. Assume the pretrained LASER embeddings are x_p and y_p and the custom

LASER embeddings are x_c and y_c. We can write the combined score $S(x, y)$ as follows:

$$S(x, y) = S_{mg}(x_p, y_p) + S_{mg}(x_c, y_c) + S_{cl}(x_p, y_p) \quad (3)$$

where $S_{mg}()$ indicates margin distance and $S_{cl}()$ indicates classifier distance. We choose to use a simple sum instead of using trainable weights because the provided parallel data that could be used to train the weights is very specific and could result in biased estimates of the weights.

We also experiment with minimum-maximum normalization that we found very useful in the case of Khmer. For this normalization each component score in Equation 3 is modified as follows:

$$S_{norm} = \frac{S - S_{min}}{S_{max} - S_{min}} \quad (4)$$

where S_{min} and S_{max} are the minimum and maximum scores over all the pairs.

3 Experimental Results

In this section we first present the results of various experiments to arrive at the final system architecture for both languages in Section 3.1. An internal system with a small architecture is used for fast turn-around. This is followed by running experiments with the final architecture using the official scripts provided by the organizers for both the from scratch and mBART settings.

3.1 Development Experiments

This section outlines various development experiments for Pashto and Khmer. As mentioned above an internal system with a small configuration is used to compare different configurations. The sacreBLEU scores for Pashto are shown in Table 4 while those for Khmer are in Table 5.

	Dev. Set	Test Set
B	7.4	8.4
C	9.3	9.3
B + C	9.2	10.4
B + C + Cl	9.5	10.5
B + C + Cl (BL)	8.3	9.6

Table 4: Pashto Development results (in SacreBLEU) for different configurations on development and test sets. B stands for baseline, C for custom, Cl for classifier and BL for BLING

	Dev. Set	Test Set
B	8.8	7.0
C	4.3	3.6
C (BL)	6.5	5.2
B + C (BL)	9.5	7.6
B + C + Cl (BL)	9.9	8

Table 5: Khmer Development results (in SacreBLEU) for different configurations on development and test sets.B stands for baseline, C for custom, Cl for classifier and BL for BLING.B+C+Cl result for Khmer uses minimum-maximum normalization.

From the two tables we can see that there is some significant difference in behavior between Pashto and Khmer. This can be summarized as follows:

- While custom LASER is better than pretrained LASER for Pashto it is worse for Khmer. We attribute this to the existence of Khmer and absence of Pashto in pretrained LASER. For Pashto, even with some small parallel data and synthetic data we can see some nice gains.
- BLING language filtering is crucial for Khmer while it hurts a bit for Pashto. We attribute this to the larger size and the noisier nature (from the view point of having more English words in the source side) of the Khmer data.
- Even if the custom LASER for Khmer is significantly worse than the pretrained one it helps when combined with the baseline.

3.2 Final Experiments

Based on the above observations, we decided to have our configurations for the final experiments of the two languages as follows:

- Use BLING filtering for Khmer but not for Pashto.
- Use the combined scores of pretrained LASER, custom LASER and classifier for both Pashto and Khmer.
- Experiment with and without min-max normalization.

The results using both from scratch (Full) and mBART (FT) settings as supplied by the organizers are shown in Table 6.

	Mode	Base	Ensemble	
			min-max	No norm
Ps-En	Full	10.04	10.12	10.05
	FT	11.61	11.99	12.38
Km-En	Full	7.16	7.88	6.36
	FT	10.56	11.12	9.02

Table 6: Final results in SacreBLEU on devtest set. Full stands for from Scratch and FT for mBART.

Based on the results in the table our submission used minimum-maximum normalization for Khmer but not for Pashto. By looking into the unnormalized scores we found that for Khmer they tend to be dominated by the classifier score, undermining both the baseline and custom LASER, and hence the normalization helps to bring all scores to the same dynamic range.

4 Summary

This paper present the description of our submission to WMT20 sentence filtering task. By building custom LASER and a classifier to distinguish positive and negative pairs. For the mBART setup our method shows 7% and 5% relative improvement in sacreBLEU score on the test set for Pashto and Khmer respectively.There are a lot of extensions along the proposed directions to improve sentence filtering for the low resource setting.

Abstract

This paper describes the joint submission of Universitat d'Alacant and Prompsit Language Engineering to the WMT 2020 shared task on parallel corpus filtering. Our submission, based on the free/open-source tool Bicleaner, enhances it with Extremely Randomised Trees and lexical similarity features that account for the frequency of the words in the parallel sentences to determine if two sentences are parallel. To train this classifier we used the clean corpora provided for the task and synthetic noisy parallel sentences. In addition we re-score the output of Bicleaner using character-level language models and n-gram saturation.

1 Introduction

This paper describes the joint submission of Universitat d'Alacant and Prompsit Language Engineering to the parallel corpus filtering shared task at the Fifth Conference on Machine Translation (WMT 2020). Our submission is built upon Bicleaner (Sánchez-Cartagena et al., 2018),[1] a widely-used free/open-source tool for detecting noisy parallel sentences that participated in the 2018 edition of this shared task and ranked fourth out of 17 submissions on one of the sub-tasks. We provide quality scores for the sentence pairs provided by the organiser without re-aligning them.

The 2020 edition of the parallel corpus filtering shared task focuses on two under-resourced Asian languages paired with English: Khmer and Pashto. Khmer (km) is the official language of Cambodia and is spoken circa 16 million people in Cambodia, Vietnam and Thailand.[2] There are about 500k English–Khmer parallel sentences in OPUS,[3] mainly belonging to narrow domains like software products and religion. Pashto (ps) is spoken by around 40 million people in Pakistan and in Afghanistan, where it is official together with Persian.[4] There are around 100k English–Pastho parallel sentence in OPUS, most of which belong to the software domain.

Detecting noisy parallel sentences for under-resourced language pairs, like those addressed in this shared task, is challenging. Pastho is not directly supported by LASER (Schwenk and Douze, 2017), although it supports other Iranian languages, and there are few bilingual resources for building the Bicleaner's models.

Bicleaner is based on a classifier that assesses whether a pair of sentences are mutual translations or not. It is trained on a parallel corpus (positive samples) and on an automatically corrupted version of the same corpus (negative samples). The most important features used by the classifier are lexical similarity scores obtained with the help of probabilistic bilingual dictionaries, which are also extracted from the parallel corpus. Our submission improves the performance of the version of Bicleaner that took part in the 2018 shared task in multiple ways: a new classification algorithm, new lexical features that account for the frequency of the words in the parallel sentences, and a novel way of generating corrupted pairs of sentences. In addition, we re-score the output of Bicleaner combining character-level language models and an n-gram saturation scorer in a linear combination whose parameters are determined by fine-tuning the MBART model provided by the organisers of the shared task.

The rest of the paper is organised as follows. Section 2 describes the Bicleaner classifier whereas Section 3 explains how the score produced by the

Online, November 19–20, 2020.

classifier is combined with the information provided by character-level language models and an n-gram saturation algorithm to produce the submitted score. Section 4 then describes the process followed to build the submission, and Section 5 lists related approaches. The paper ends with some concluding remarks.

2 Bicleaner classifier

Bicleaner is based on an automatic classifier that produces a score for a pair of sentences representing the probability that they are mutual translations. Random Forests (Breiman, 2001), the classification algorithm used in the 2018 submission, has been replaced by Extremely-Randomised Trees (Geurts et al., 2006) because the latter performed best on preliminary experiments.

The Extremely Randomised Trees classification algorithm works by selecting at each internal node the *best* feature from a sub-set of features selected at random from the whole set of features F, and using a random cut-off point. The hyper-parameters controlling the training of these classifiers are therefore the method used to rank the features and select the best one, the size of the subset of features selected at random, and the number of trees to be used. To select the best hyper-parameters we performed a grid search with the following hyper-parameter values. For the ranking we tried with Gini importance (Breiman et al., 1984, Ch. 4) and information gain; for the size of the sub-set of features we tried with $|F|$, $log_2|F|$ and $\sqrt{|F|}$; for the number of trees we tried with 100, 200, 300, 400 and 500.

The features we used can be split in two groups: those that account for the lexical similarity of the two sentences, and those based on shallow properties of the sentences.

2.1 Lexical features

Bilingual lexical similarity is assessed by means of the lexical feature $\mathrm{Qmax}(S, \Theta, d)$, which was first described by Sánchez-Cartagena et al. (2018) and is inspired by the translation probabilities used in statistical machine translation (Koehn, 2009). It is defined as:

$$\mathrm{Qmax}(S, \Theta, d) = \left(\prod_{t \in \Theta} \max_{s \in \mathcal{S} \cup \{\mathrm{NULL}\}} p(t|s; d) \right)^{\frac{1}{|\Theta|}}$$

where, S is a source-language (SL) sentence, $\mathcal{S}$ is a set with the tokens in S, Θ is a set with the tokens in the target-language (TL) sentence T that appear at least once in the SL-to-TL probabilistic bilingual dictionary d, and $p(t|s; d)$ stands for the translation probability of the target token t given the source token s according to the bilingual dictionary d. A smoothing is applied if, for a token t, $\max_{s \in \mathcal{S} \cup \{\mathrm{NULL}\}} p(t|s; d)$ equals zero; in that case, this expression is set to the value of the smallest probability in d divided by 10. One can interpret that, in this case, the dictionary is providing evidence that t is unlikely to be the translation of any of the tokens in S. It is worth noting that this case differs from the case in which a token $t \in T$ does not appear in the dictionary at all; in that case, no evidence, either positive or negative, is available for it. This is why Qmax is only computed for the tokens in Θ instead of doing so for all the tokens in T.

The informativeness of Qmax strongly depends on the coverage of the probabilistic bilingual dictionary used. To measure the coverage of this dictionary, the feature Qmax is complemented with two additional features: $\mathrm{CoverT}(T, d)$, which returns the percentage of unique tokens in T appearing in d, and $\mathrm{CoverTS}(S, T, d)$, which returns the percentage of unique tokens in T that appear in d associated with at least one token in S. All these features are also computed in the reverse direction: $\mathrm{Qmax}(\Theta, S, d')$, $\mathrm{CoverS}(S, d')$, and $\mathrm{CoverST}(T, S, d')$, where d' is a TL-to-SL probabilistic bilingual dictionary.

Even though low-frequency words usually have more discriminatory power (Ramos, 2003), the original formulation of the Bicleaner lexical features did not take into account word frequency in any way. In order to allow the classifier to give different weights to words from different frequency ranks, we re-formulated the lexical features: Qmax now becomes a set of features $\{\mathrm{Qmax}_q(S, \Theta, d, R) \mid q \in [1, 4]\}$. While the summation in the original Qmax was computed for all the tokens in Θ, in Qmax_q it is only computed for those tokens in Θ that appear in the quartile $q \in [1, 4]$ of the ranking of tokens R. R sorts tokens by the logarithm of their relative frequency in a monolingual corpus; in this way, quartile $q = 1$ contains a large amount of tokens with low frequency, while quartile $q = 4$ contains fewer tokens with high frequency.[5] The same adaptation is applied to obtain

[5] Preliminary experiments showed that no gain is obtained by dividing word frequencies in more than four groups.

the set of features $\{\text{CoverS}_q(T, d) \mid q \in [1, 4]\}$ and $\{\text{CoverST}_q(S, T, d) \mid q \in [1, 4]\}$. As in the original Bicleaner, these features were also computed in the reverse direction.

2.2 Shallow features

Shallow features do not make use of bilingual lexical information and are aimed at complementing the lexical features, which may not be reliable enough in sentence pairs with poor dictionary coverage. The shallow features used can be further split into those that model sentence length and those that identify tokens and characters that give hints about the parallelness of a pair of sentences.

Features that model sentence length are based on the assumption that the ratio between the lengths of a pair of parallel sentences is fairly constant for a given language pair. Hence, sentence pairs that deviate too much from this ratio are not likely to be parallel. We measure how close is the ratio of a given pair of sentences to the expected one as the probability mass function of a Poisson distribution. We also provide the raw lengths to the classifier. The complete list of features based on sentence length is the following. Each of these features is computed independently for the SL sentence S and for the TL sentence T of the pair.

- Likelihood of having a TL segment T with length (in tokens) l_T given l_S, the length of the SL segment S, and r_{ts}, the ratio between the length of TL and SL computed on a training parallel corpus; likelihood is computed as $Pr(X = l_T; \lambda = l_S \cdot r_{ts})$. This feature is also computed for S: $Pr(X = l_S; \lambda = l_T \cdot r_{st})$. Note that $Pr(X = k; \lambda = L) = \frac{e^{-L} \cdot L^k}{k!}$.
- Number of tokens in the sentence.
- Number of characters in the sentence.
- Average token length (in characters) in the sentence.

Parallel pairs of sentences are also likely to share numerical expressions, punctuation marks and proper nouns. The following features aim at leveraging that information. Each of these features is computed independently for S and T.

- Number of punctuation marks of each type.
- Proportion of numerical expressions in the sentence that can be found in the other sentence of the pair.
- Proportion of capitalised tokens in the sentence that can be found in the other sentence of the pair.

Finally, character counts can also be considered hints for parallelness. They are taken into account by the following features, which are computed independently for S and T:

- Number of characters in each of the main Unicode classes.
- Number of different characters.
- Number of occurrences of the three most frequent characters, normalised by sentence length.
- Entropy of the string, considering each character as an event whose probability is proportional to the number of occurrences of the character in the sentence.
- Maximum number of consecutive repetitions of the same character.

Overall, 92 shallow features are used.

2.3 Modelling noise

For training the Bicleaner classifier, positive and negative samples are used. The positive samples are those found in the original parallel corpus. The negative samples are generated by corrupting the sentences in that corpus as explained next.

Three types of synthetic noise are applied for corrupting the sentences:

- wrong alignment: parallel segments are randomly re-aligned to produce pairs of segments that are not parallel;
- wrong segmentation: one of the sentences in the pair is truncated: a suffix starting from a random position is removed, therefore emulating an error in sentence segmentation; and
- word replacement: a random number of words in one of the sentences of the pair is replaced by other words with similar frequency as computed on a monolingual corpus.[6]

The amount of corrupted sentences we generated equals the the size of the original parallel corpus,

[6]The ranking of token frequencies R described in Section 2.1 was used for this replacements.

and the three types of synthetic noise were applied in the same proportion. The classifier is therefore trained on a set of sentences twice as large as the original parallel corpus. This strategy differs from the one followed in the 2018 submission (Sánchez-Cartagena et al., 2018) for generating corrupted sentences, where only the "wrong alignment" type of noise was used.

3 Re-scoring

Subsampling 5 million words from the raw corpus based on the score described in the previous section ensures that NMT systems are trained on parallel data. However, some of the selected training parallel samples may not bring useful information and replacing them with other, more informative samples could improve the performance of the resulting NMT systems. We hypothesise that two main reasons could make a pair of sentences which are mutual translations non-informative: i) sentences are not fluent enough and hence very different from those that will be translated with the resulting NMT systems: lists of keywords or website menus are examples of such non-fluent sentences; and ii) the pair of sentences is too similar to other training samples.

To take into account these additional factors, the final score assigned to each sentence pair was computed as follows. First, each sentence received a preliminary score, $\mathrm{prescore}$, computed as:

$$\mathrm{prescore}(s,t) = \lambda \cdot \mathrm{bicleaner}(S,T) + (1-\lambda) \cdot \min(\mathrm{fluency}_s(S), \mathrm{fluency}_t(T)))$$

where S and T are respectively the SL and TL sentence, $\mathrm{bicleaner}$ is the score described in Section 2, and $\mathrm{fluency}_s$ and $\mathrm{fluency}_t$ denote, respectively, fluency scores in the SL and in the TL provided by character language models.[7]

Fluency scores were computed as the normalised perplexity of the sentence according to a 7-gram character language model estimated with KenLM (Heafield, 2011). Normalisation was aimed at placing the perplexities in the $[0,1]$ interval and consisted on a linear transformation that ensured that the values in the raw corpus had a mean of 0.5 and standard deviation of 0.25. Assuming that the perplexities follow a normal distribution, 95% of the values fall into the desired range. Those values with score lower than 0 or higher than 1 after the transformation were set to 0 and 1, respectively.

After computing $\mathrm{prescore}$, sentence pairs were sorted by that score in descending order, and the score of those pairs for which all their 3-grams could be found in sentences with a higher score was multiplied by a penalty β to promote diversity in the subsampled corpus.

The values of the parameters λ and β, that control the contribution of parallelness, fluency and novelty to the final score were optimised so as to maximise the BLEU score obtained after fine tuning the MBART model provided by the task organisers. The Nelder-Mead algorithm (Nelder and Mead, 1965), which does not require gradient computations, was used.

4 Building the submission

This section describes the process followed to build our submission, which comprised selection of training data, corpora preprocessing, classifier training and evaluation of different alternatives for some of the steps.

4.1 Data used

For both language pairs, the classifier training data was built from the concatenation of all the clean parallel corpora provided by the shared-task organisers. The length ratios used in shallow features were computed on the same data, as well as the bilingual dictionaries. In order to build the dictionaries, the parallel sentences were word-aligned with `MGIZA++`.[8] Alignments were symmetrised with the heuristic *grow-diag-final* and the probabilities in the bilingual dictionaries were estimated afterwards by maximum likelihood.

The Wikipedia monolingual corpus provided by the organisers was used to compute the word frequencies for word ranking R as described in Section 2.1. The same monolingual data was used to train character language models. Pashto and Khmer models were trained on the complete data. A different English language model was trained for each language pair on a random sample of the

[7] Values of λ close to 1.0 make lists of keywords or website menus that are mutual translations to have the highest scores. Value of λ around 0.5 make the top scored segment pairs to be fluent, complete grammatical sentences. Values of λ close to 0.0 make fluent but non-parallel sentences to receive the highest scores.

[8] https://github.com/moses-smt/mgiza.git

English Wikipedia corpus that matched the size of the Pashto/Khmer Wikipedia corpus.

4.2 Pre-filtering

The clean parallel data provided by the organisers was filtered before their use. Those parallel sentences in which at least one side contain less than 20% of characters in the Unicode range of the corresponding language were discarded. The remaining parallel sentences were deduplicated.

The raw sentence pairs to be scored were also pre-processed with a series of heuristic rules: the score was set to zero if any of the conditions was met. These rules were aimed at detecting segments with evident flaws and speeding up the subsequent steps. The rules were aimed at detecting the following defects in the parallel sentences:

- Wrong language: same Unicode filtering applied to the clean corpora (see above).
- Too long sentences: those with more than 1024 characters.
- Untranslated: SL and TL segments are identical after removing numerical expressions and punctuation marks.
- Not fluent: the sentence contain elements such as URLs, arithmetic operators, too many parentheses, escaped Unicode characters, and other common defects that arise when crawling parallel corpora from the web. These elements were detected by means of regular expressions.

4.3 Tokenisation and word segmentation

Tokenization and subword segmentation have shown to improve the recall of the probabilistic dictionaries used to obtain the lexical features described in Section 2.1. We experimented with the following tokenisation and subword segmentation methods, which were applied to the clean data as well as to the raw sentences to be scored:

- Rule-based tokenisation (`tok`) for Pashto, Khmer and English, as provided by the tool Polyglot (Al-Rfou et al., 2013);
- Rule-based tokenisation plus word morphological segmentation with Morfessor (`tok-morph`). For this we used, after tokenisation, the pre-trained models for Morfessor (Virpioja et al., 2013) included in Polyglot.

4.4 Training Bicleaner

As previously mentioned, the probabilistic bilingual dictionaries were obtained from the same parallel corpus used to train the classifier. This strategy has an important drawback. While almost all words would be found in the bilingual dictionaries when training the classifier, the coverage would be much smaller when classifying the raw sentences because of the small amount of parallel data available. In order to close the gap between training and classification, we removed some dictionary entries during training. Specifically, we removed the least frequent entries so as to ensure that the coverage of the truncated dictionaries on the training data matches the coverage of the full dictionaries on the raw sentences to be scored.

4.5 Results

Table 1 depicts the results obtained on the development environment during the preparation of the submission. The system that produced the scores for our final submission is shown in bold.

We firstly evaluated the different tokenisation alternatives described in Section 4.3, and applied the re-scoring scheme described in Section 3 on top of the best performing one. The results show that the tokenisation with Polyglot without any kind of subword segmentation (`tok`) leads to the best results. It is also worth mentioning the poor performance obtained with morphological segmentation, which needs to be studied more carefully. Moreover, re-scoring for increased fluency and diversity further improved the results.

Table 1 also shows the results obtained by the baseline LASER model,[9] which was consistently outperformed by Bicleaner. Comparing the results of the version of Bicleaner used in this submission with that used in 2018 also shows that the changes introduced bring a positive impact.

5 Related work

A shared task on parallel corpus filtering was part of the WMT conference programme for the first time in 2018 (Koehn et al., 2018). That year the task was targeted at a high-resource scenario. NMT models, which already provide the probability of a

[9] These results do not exactly match those published at `http://www.statmt.org/wmt20/parallel-corpus-filtering.html`, probably because of differences in the GPU hardware or random initialization seed.

	Khmer–English		Pashto–English

Table 1: BLEU scores obtained by the different configurations evaluated for Khmer–English and Pashto–English on the development environment provided by the organisers.

TL sentence given an SL sentence, emerged as the dominant approach (Junczys-Dowmunt, 2018).

Last year's edition was focused on a low-resource scenario (Koehn et al., 2019), where parallel data big enough to build NMT models that provide reliable TL probability distributions was not available. The best performing model was LASER, a method based on multilingual sentence embeddings (Chaudhary et al., 2019) that takes advantage of the data available for multiple language pairs. In fact, a LASER model trained on 93 languages is the baseline model published by the organisers for this edition of the shared task.

Unlike LASER, our submission is mainly based on lexical similarity scores analogous to those used in statistical machine translation. They are computed only on parallel data, without any kind of transfer learning from other language pairs. The approach we follow to detect sentences that are mutual translations is similar to the one by Munteanu and Marcu (2005) for detecting parallel sentences in comparable corpora. However, we use a larger set of shallow features not related to lexical similarity and follow a more sophisticated method for generating negative samples.

Concerning our re-scoring strategy for including information about fluency and diversity, participants from past editions also used these attributes to score sentences. For instance, Axelrod et al. (2019) and Vázquez et al. (2019) devised a scoring strategy under the assumption that parallel sentences should have similar monolingual language model perplexities, and many other submissions included a penalty for repetitive sentences (González-Rubio, 2019; Erdmann and Gwinnup, 2019; Bernier-Colborne and Lo, 2019). Nevertheless, to the best of our knowledge, our approach is the first one that directly optimises the weight of these attributes towards an automatic translation evaluation metric.

6 Concluding remarks

We described the joint submission of Universitat d'Alacant and Prompsit Language Engineering to the parallel corpus filtering shared task at the Fifth Conference on Machine Translation (WMT 2020). Our submission is based on Bicleaner, an open source tool based on a classifier that uses lexical similarity features inspired in the translation probabilities used in statistical machine translation.

We presented a series of improvements over the version of Bicleaner that participated in the 2018 edition of the shared task, namely a better classifier, more sophisticated generation of negative samples and a reformulation of the lexical similarity scores which takes into account word frequency. We showed that these improvements are effective and they allowed our submission to outperform LASER, a state-of-the-art method based on multilingual sentence embeddings. Moreover, combining Bicleaner scores with scores that account for fluency and diversity further improved the results.

We plan to keep exploring subword segmentation algorithms that help to fight data sparseness when computing lexical similarity scores with the help of bilingual dictionaries. We also aim at integrating word embeddings into lexical similarity scores, which would allow us to leverage monolingual data in a more effective way.

Abstract

This document describes an exploratory look into the Parallel Corpus Filtering Shared Task in WMT20. We submitted scores for both Pashto-English and Khmer-English systems combining multiple techniques like monolingual language model scores, length based filters, language ID filters with confidence and norm of embedings.

1 Introduction

For this task the participants were provided with a corpus of parallel data in Pashto-English (ps-en) and Khmer-English (km-en). Additional parallel and monolingual datasets were also provided. The task organizers built neural machine translation (NMT) systems from the scores produced, based on parallel training sets of 5 million words. These systems are sensitive towards noise (Khayrallah and Koehn, 2018) and thus, it becomes important to separate the useful data from the noise. We view the task as data that passes through a pipeline of filters in order to give us the best possible selection of 5 million words in the end.

We determined that language ID filtering is a very strong pre-processing filter and inducting confidence scores is not needed. We also determined that monolingual Language models can help us in selecting sentences even if both the source and target language models are independent of each other. Finally, using using the length of a sentence as a filter helps us create a better NMT system.

We also learn that statistical intuitions do not easily extend to neural embeddings.

2 Baseline

The idea behind our baseline system is to use the cosine distance between two multilingual representations as a notion of parallelism between sentences embedded in the same space. The tool we use for this is LASER[1] which uses an encoder-decoder architecture to train a multilingual sentence representation model. It has been shown by Artetxe and Schwenk (2018b) that LASER is effective at zero-shot cross-lingual natural language inference in the XNLI dataset which makes it promising for this task involving low-resource languages. Koehn et al. (2019) has shown this to be a strong baseline.

We follow the work done by Artetxe and Schwenk (2018a) and begin by generating multilingual sentence embeddings using LASER. The LASER score is a function of the margin between the cosine similarity between a given candidate and it's k nearest neighbors[2]:

Let f(x,y) =

$$\sum_{z \epsilon NN_k(x)} \frac{cos(x,z)}{2k} + \sum_{z \epsilon NN_k(y)} \frac{cos(y,z)}{2k}$$

LASER score(x,y) = margin(cos(x,y),f(x,y))

We experiment with the following definitions of margin:

- **Absolute:** margin(a,b) = a
  Essentially just cosine similarity.
- **Distance:** margin(a,b) = a - b
  Subtracting the average cosine similarity from that of the given candidate. We use this when there are certain points that are extraordinarily close to many other data points and thus, degrade the quality of nearest neighbors.
- **Ratio:** margin(a,b) = a / b
  This is the ratio between the candidate and the average cosine of its nearest neighbors in both directions.

[1] https://github.com/facebookresearch/LASER

[2] cos(x,y) here refers to cosine similarity between the vectors x and y

Proceedings of the 5th Conference on Machine Translation (WMT), pages 959–965

We also experiment with the following techniques of candidate generation:

- **Intersection:**
  Each source sentence is aligned with exactly one best scoring target sentence. Some target sentences may be aligned with multiple source sentences or with none. We repeat this process in the opposite direction and take the intersection of the 2 alignments

- **Max score:**
  We repeat the process used to generate candidates in Intersection, except we select the alignment with the highest score instead of discarding all inconsistent alignments

We find that the best settings were margin set to ratio, candidate generation set to max-score and k set to 4. Note that this list of nearest neighbors does not include duplicates, so even if a given sentence has multiple occurrences in the corpus, it would have (at most) one entry in the list (Chaudhary et al., 2019). These scores are in the range of [0,1].

The BLEU scores obtained by these systems are 11.16 for Pashto and 9.65 for Khmer.

3 Language ID

For our first step, we try to predict the most probable language of a given sentence using use fastText (Joulin et al., 2016). We use the pre-trained model released by the authors that is trained to identify over 170 languages including Pashto, Khmer and English. The intuition behind it is that when working in a bilingual setting, sentences from other languages or code-mixed sentences will be harmful to the MT system. We call this simple language ID

if source = ps|km and target = en **then**
  langID score = LASER score
else
  langID score = 0
end if

An additional idea that we incorporate is how confident we are when predicting the language of a sentence. For example, if we have a sentence where the probability of the target sentence being English is 0.9 and we have another sentence where the probability of the target sentence being English is 0.3, then given the same LASER scores, we would want to give preference to the sentence pair where the probability of the target sentence is 0.9. We do this for both the source and target language.

We try to only keep sentence pairs where we are confident about both the source and target language being correct. We implement this notion by setting a cutoff c for the language ID probability. We call this confident language ID

if prob(src=ps|km) $>$ c and prob(tgt=en) $>$ c **then**
  confidence = prob(src=ps|km) $\cdot$ prob(tgt=en)
else
  confidence = 0
end if
langID score = LASER score $\cdot$ confidence

Where prob(p=q) is the probability of sentence p being from language q.

We show our results for Pashto in Table 1 and make the following observations.

- There is an overall increase in BLEU.
- Simple language ID seems to be better than Confident language ID by a small margin.
- Confident language ID, has a local minima at a cutoff of 0.75
- The scores in confident language ID tend to decrease sharply after a cutoff of 0.8.

This leads us to believe that while good for identifying the language, the confidence scores are not as strong as the LASER scores.

We experiment by including scores if they are within the top 3 predicted languages but see no significant change in scores.

We also experiment by adding the confidence instead of multiplying it in confident language ID but see no significant change in the BLEU scores.

As a result of our observations, we only perform Simple Language ID for Khmer, giving us a BLEU score of 11.51 for Pashto and 10.04 for Khmer.

4 Norm of embeddings as a filter[3]

Liu et al. (2020) showed us that the norm of an embedding can represent how frequent and how context insensitive the embedding is. Essentially, smaller norms represent frequent and context-insensitive rare words. There is an implicit assumption here that the embedding size is large enough to incorporate all the information present in a sentence.

[3] *Note: Throughout this section we shall be using the terms "vector" and "embedding" interchangeably.*

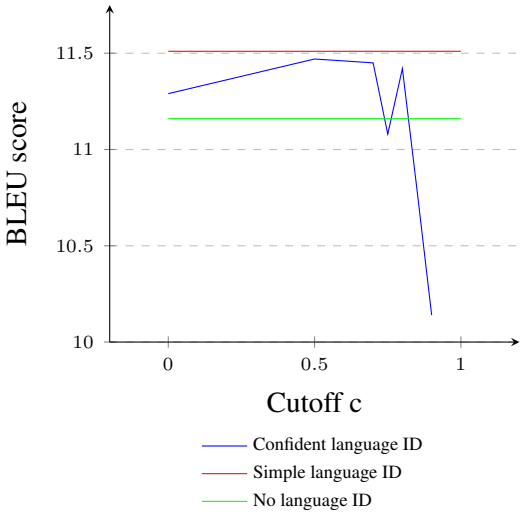

Figure 1: Cutoff vs BLEU scores for Pashto

For a vector $x_i = [x_{i1}, x_{i2}, ..., x_{in}]$ the norm of the vector is

$$norm(x_i) = \sqrt{x_{i1}^2 + x_{i2}^2 + ... + x_{in}^2}$$

We interpret the norm of an embedding as a measure of the confidence we have in the embedding of a sentence. The reason we do this is that neural methods by their very nature are data hungry and susceptible to noise. We are working in a low-resource condition because of which it will be harder to learn about sentences with context-sensitive words. Additionally, it would be harder to learn about sentences with low-frequency words making their embeddings less reliable, thus, leading to a lower quality MT system.

We run 2 sets of experiments on the LASER embeddings of the sentences.

- We assume that the elements in each vector are comparable, i.e. on the same scale. We simply take the norm of the embedding in this case.

- We assume that the elements in a vector are not directly comparable. In this case, we compute the z-score of each element and take the norm of the z-scores. z-score can be thought of as how many standard deviations is a given element away from it's mean. Thus it gives each element a relative value, making them comparable. We finally take the norm of the z-scores.

  $$z\text{-}score = \frac{x-\mu}{\sigma}$$

  where μ is the mean and σ is the standard deviation of that particular element across all the vectors that have a non-zero langID score.

The langID scores we have until now are in the range [0,1], while the norm of the embeddings theoretically have a range of $[0, \infty)$. To ensemble the langID scores with the norm-scores, we need to bring the distributions within a comparable range. We do this by applying min-max normalization.

Let $x = [x_1, x_2, ..., x_n]$
where
x_i = norm (embedding (i^{th} vector))
or
x_i = norm (z-score (embedding (i^{th} vector)))
for all vectors with langID score $\neq 0$ **do**

$$\text{normalized } (x_i) = \frac{x_i - min(x)}{max(x) - min(x)}$$

end for
norm score = langID score - normalized

We observe that in both the cases, there are very few observations with a really high norm because of which over 95% of the norm scores remained the same up to 6^{th} or more decimal place. To counter this, we set the langID scores of these embeddings to 0 and repeat the process recursively till we see an impact on the 5 million token subselected corpus.

We make the following observations

- We see a drastic reduction in the Pashto BLEU scores from 11.51 to 9.76 when we use z-scores.

- When we do not use the z-scores, we see a decrease in the BLEU score from 11.51 to 11.37 for Pashto. and an increase from 10.04 to 10.05 for Khmer. In both the cases the change is really small and not significant.

- Manual observation here shows that sentences with big URL's were filtered out automatically without any explicitly stated rule.

- Being more aggressive with the number of loops led to a drastic decrease in BLEU scores.

We finally ran experiments where we gave a preference to only large norms and an experiment where we gave a preference to both very large norms and to very small norms. In both the cases we had really bad scores leading to the conclusion that the norm of LASER embeddings is not a good

filter. Because of this poor performance when relied on aggressively, we decided not to use it in our final submission.

We also ran the same experiments using fasttext generated embeddings (Bojanowski et al., 2017) but that had poor results as well.

5 Monolingual Language Models

The motivation behind using Monolingual Language Models is that we want to learn about sentence pairs that have a high likelihood of coming up in the test data. Ideally we would want both the sides of the corpus to have a high probability of coming up but we also realize it will often not be the case. Thus, we make these language models independent of each other. We take inspiration from Axelrod et al. (2019) and modify the work of Junczys-Dowmunt (2018) to come up with a language model filter. Junczys-Dowmunt (2018) achieved the highest ranking score in WMT'18 and to do so they define $H_M(.|.)$ as the word-normalized conditional cross-entropy of the probability distribution $P_M(.|.)$ for a model M:

$$H_M(y) = -\frac{1}{y}\sum_{t=1}^{|y|} logP_M(y_t|y_{<t})$$

We use this as a measure of how fluent a given sentence is. Lower scores indicate a better sentence in this case.

While Axelrod et al. (2019) do create n-gram language models, they hope that language models trained on similar but not parallel texts to have similar perplexities over each half of a parallel test set of the parallel corpus. This method does not leverage the simple fact that we have more data for one of the languages. This method also assumes a close relationship between the frequencies of letters which might not always be the case. Finally it does not leverage the expressive power of neural language models. In order to improve on this, we propose Neural Language Models that are completely independent of each other.

5.1 Pre-processing

We first tokenize our data using Sentencepiece (Kudo and Richardson, 2018). We set an upper limit of 5,000 on the vocabulary size for Pashto and Khmer, and an upper limit of 50,000 for the English vocabulary. This is done at both the character and word level and also both with and without splitting at whitespace. We also reverse the data to simulate right-to-left prediction of words. Thus we have 8 possible tokenizations for every possible sentence.

Figure 3: Language Model: Wiki103 architecture

5.2 Language Model Architecture

For our Language Models, we use fairseq (Ott et al., 2019) to implement the architecture given in Figure 2.

We also create a Language Model using the architecture given by Baevski and Auli (2019) with parameters as given in Figure 3.

We use 2 different models because while it is tempting to use deeper and more sophisticated models, we need to have enough data to train it sufficiently. If sufficient data is absent, it is in general better to train simpler models.

In total we have 16 language models for each language. In each case, we train the model in 2 further ways. In the first case, we keep the CommonCrawl monolingual data as the training set and keep the Wikipedia monolingual data as the development set. In the second case, we augment the CommonCrawl data with Wikipeda data by oversampling. We make the number of lines taken by the wikipedia data be between 40-50% of the number of lines taken by the CommonCrawl data.

During training, the word level language models that were not split on white-space were taking too much time to train. As a result we had to halt their training and use the best checkpoint achieved till then.

5.3 Evaluating the Language models

We evaluated the Language Models by using their word normalized cross entropy as defined in Equation 5. We find that the scores we got were extremely similar whether we used just the CommonCrawl data or whether we augmented it with the Wikipedia data. In addition, the Transformer architecture gave us better results.

We evaluate our created development set and find that the word-level left-to-right and character level left-to-right language models had the lowest perplexities of their respective groups.[4] Additionally, the language models created for Pashto were relatively much stronger than the language models created for Khmer simply because of the script in which Khmer is written.

5.4 Normalising LM-scores

Once again, the values of langID scores range between [0,1] and our language models scores range between [0,∞]. In order to ensemble them, we need to bring them to a comparable scale. We again try to use min-max normalization to change the range of the cross entropy values to be [0,1]. Once again we run into the same problem where the value of maximum is so high that the change bought about in langID scores was negligible. Instead of going for a recursive approach, we take a more aggressive approach this time. We average over the cross entropy values of sentences that we would have selected using langID scores and we replace the max(crossEntropy) with an empirically chosen value close to it.

Let $x = [x_1, x_2, ..., x_n]$
where x_i = cross entropy (i^{th} vector)
for all vectors **do**

$$\text{new entropy } (x_i) = \frac{x_i - min(x)}{max(x) - min(x)}$$

end for
LM score = langID score - new entropy

We display the results for only Pashto and a few English Pashto ensemble models in Figure 4.

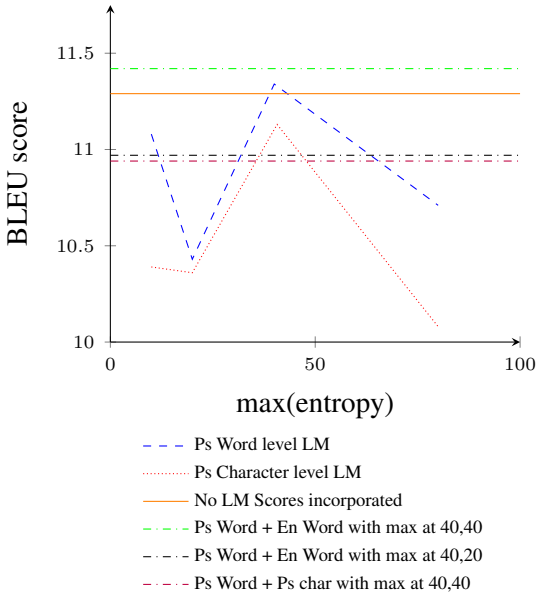

Figure 4: BLEU score vs max(entropy) for Pashto

We can also see that just the word level language models perform better than both the character level models and the Word + Character ensemble models.[5] Similar trends were observed for Khmer.

5.5 Length-based filters

We observed that our language model had a tendency to pick proper nouns. While we want our language model to learn about names, we don't want to select them over sentences because our translation is model is based on sentences. To counteract this, we decided to add a simple length based filters to Pashto and English. Since they both used white spaces and have an almost 1 to 1 mapping, we added a penalty of -1 to their score if any of the sentences were below 0, 5 and 8 in length. We call this cutoff value lc. We decide on a penalty of -1 because the maximum score that any sentence can get right now is 1. This results in that sentence not being selected at all. Following work described in Koehn et al. (2019) we also add a penalty term of -1 whenever either the source or the target sentence was over 3 times it's counterpart in length. We call this length ratio cutoff lr

if len(src) $<$ lc and len(tgt) $<$ lc **then**
    LM score = LM score -1
end if
if len(src)/len(tgt) $>$ lr or len(tgt)/len(src) $>$ lr **then**
    LM score = LM score - 1

[4]Experiments on ensembling these models were still running at the time of submission

[5]We observed that the perplexities on the english side tended to be about half of Pashto and one fourth of Khmer.

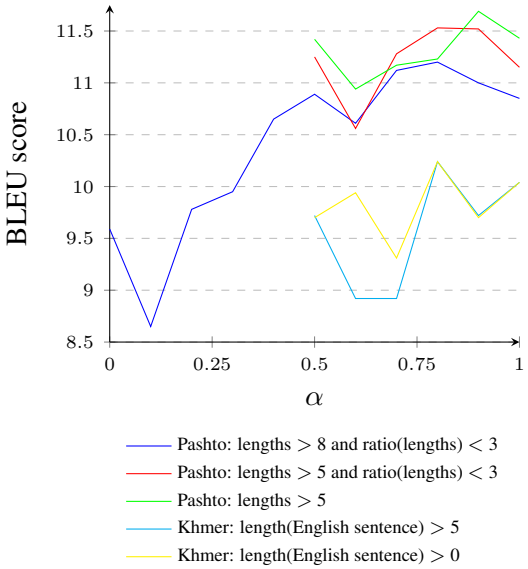

Figure 5: Change in BLEU scores with respect to the amount of weight given to Language Models

end if

In the Khmer-English case, we only experimented with a sentence length on the English side since there were no clear demarcations in Khmer.

if len(tgt) $<$ lc **then**
LM score = LM score -1
end if

We then experiment with a penalty if there is an overlap of more than 60% between the tokenized texts. However this doesn't show any significant changes.

5.6 Assigning Weights to different scoring mechanisms

While we tried to give an equal weight to the Language model and LASER scores, we had no good reason to believe that we should. We introduced a hyperparameter α which lies between 0 and 1, and we change the equation of LM score to be

Let $x = [x_1, x_2, ..., x_n]$
where x_i = cross entropy (i^{th} vector)
for all vectors **do**

$$\text{new entropy } (x_i) = \frac{x_i - min(x)}{40 - min(x)}$$

end for
LM score = (α)(langID score) - (1-α)(LM score)

We replaced the maximum with the value 40 from our findings in Section 5.4

We first run this on Pashto sentences with lc $>$ 8. We use those results to narrow our seaarch with lc $>$ 5 and lc $>$ 0. We then use those results to run experiments for Khmer. The combined results are shown in Figure 5

From figure 5 we can see that we have to local maximas around 0.5 and 0.8 and a global maxima at 0.8. In some cases the global maxima is at 0.9 and in some at 0.8. This leads us to believe that these are the most suitable values for the task.

6 Final Submission

Our final pipeline is as follows:

1. Obtain LASER scores for each sentence pair
2. Pass it through a language id filter where we set the LASER score to 0 if either the source or target language doesn't match
3. score the source and target half of the parallel corpus using monolingual language models
4. combine the language model scores with LASER scores
5. Apply a length based filter to remove sentences that don't provide too much information

We submit what we believe to be the 3 most robust solutions we have for each language pair. For Pashto, we apply the language id filter, then we use the Transformer architecture language model, set lr to 3 and set(α, lc) to (0.8, 5), (0.9, 0) and (0.9, 5). For Khmer, we apply the language id filter, then we use the Transformer architecture language model and set (α, lc) at (0.8, 5) and (0.8, 6). Apart from that, we also submit a scores with a filter checking for token overlap over 30%. The (α, lc) is set to (0.8, 5). At the time of submission our best score for Pashto is 11.69 and the best score for Khmer is 10.24 on the development set. The findings of the shared task presented by Koehn et al. (2020)

Dual Conditional Cross Entropy Scores and LASER Similarity Scores for the WMT20 Parallel Corpus Filtering Shared Task

Felicia Koerner **Philipp Koehn**
Center for Language and Speech Processing
Johns Hopkins University
{fkr, phi}@jhu.edu

Abstract

This paper describes our submission to the WMT20 Parallel Corpus Filtering and Alignment for Low-Resource Conditions Shared Task. This year's corpora are noisy Khmer-English and Pashto-English, with 58.3 million and 11.6 million words respectively (English token count). Our submission focuses on filtering Pashto-English, building on previously successful methods to produce two sets of scores: LASER_LM, a combination of the LASER similarity scores provided in the shared task and perplexity scores from language models, and DCCEF_DUP, dual conditional cross entropy scores combined with a duplication penalty. We improve slightly on the LASER similarity score and find that the provided clean data can successfully be supplemented with a subsampled set of the noisy data, effectively increasing the training data for the models used for dual conditional cross entropy scoring.

1 Introduction

Machine translation systems require large amounts of high quality parallel corpora for training. Neural machine translation models in particular have been found to both require more data (Koehn and Knowles, 2017), and be more sensitive to noise in training data (Khayrallah and Koehn, 2018) than statistical machine translation models. While these data can be acquired from online sources, the resulting crawled texts are often noisy and require filtering to produce large amounts of sufficiently clean training data.

2 Related Work

We refer readers to (Koehn et al., 2019) for a more detailed overview of methods for parallel corpus filtering, here we describe the most relevant methods to this work.

2.1 Rule-based Filtering

Most filtering methods employ some rule-based filtering, usually to prepare the data for other scoring methods, based on language models, classifiers, or other translation models. (Sánchez-Cartagena et al., 2018) apply hard rules to filter out data before using a classifier to score sentence pairs. (Rossenbach et al., 2018) use many rules, including limits on sentence length, Levenshtein distance, length ratio, and token ratio. We use basic language ID and overlap rules only for the Dual Conditional Cross Entropy Scores, this is described in more detail in subsection 5.1. The LASER similarity scores provided by the shared task organizers also apply a language ID filter (assigning the pair a score of 0 if either of the sentences are not recognized as the expected language).

2.2 Dual Conditional Cross Entropy Scores

The most successful scoring method in the WMT18 Shared Task on Parallel Corpus Filtering was Dual Conditional Cross Entropy Filtering (dccef) (Junczys-Dowmunt, 2018). This method trains an NMT model in both translation directions, uses these to calculate the cross-entropy for each sentence, and finally produces a score based on their agreement. As this year's task deals with low-resource languages (contrary to WMT18, which was En-De), we explore a method to bootstrap the available clean data, thus producing more training data for the intermediate NMT models required for the method (described in more detail subsection 5.2).

2.3 LASER Similarity Scores

LASER similarity scoring was the most successful scoring method of the WMT19 Shared Task on Parallel Corpus Filtering for Low-Resource Languages (Chaudhary et al., 2019). This method embeds parallel sentences with Language Agnostic SEntence

Proceedings of the 5th Conference on Machine Translation (WMT), pages 966–971
Online, November 19–20, 2020.

Representations (LASER) (Artetxe and Schwenk, 2018), and uses these to compute cosine similarity scores. This work attempts to augment LASER similarity scores with language model scores (described in more detail in subsection 4).

3 Shared Task

For this year's shared task on Parallel Corpus Filtering and Alignment for Low-Resource conditions, participants are asked to produce scores for each of the sentence pairs in the provided noisy 58.3 million-word (English token count) Khmer-English corpus and 11.6 million-word Pashto-English corpus. These scores are used to subsample sentence pairs amounting to 5 million English words. The resulting subset is evaluated by the quality of an NMT system (`fairseq` (Ott et al., 2019)) trained on this data.

Participants were given the scripts to either train the evaluation system from scratch, or use the data to fine-tune a provided pretrained MBART model. The MBART model was trained on monolingual data, the details of which are described in (Liu et al., 2020). The performance of the NMT system is measured by BLEU score on a held-out test set of Wikipedia translations. Participants may also provide re-alignments of the source and target sentences. The organizers provide clean parallel and monolingual data for both of the language pairs, as well as LASER similarity scores, a previously successful method in low-resource conditions (Chaudhary et al., 2019), (Koehn et al., 2019).

We participated in the Pashto-English track only, after finding that the model-based methods we explored did not produce meaningful scores for Khmer-English. We did not submit sentence realignments, focusing instead on sentence filtering. Our submission builds on previously successful methods from past WMT shared tasks on parallel corpus filtering to produce two scores: LASER_LM, a combination of the LASER similarity scores and perplexity scores from language models, and DCCEF_DUP, dual conditional cross entropy scores combined with a a duplication penalty. All BLEU scores listed in this paper come from systems trained from scratch and run on the provided development data.

4 LASER_LM

A shortcoming of LASER similarity scores is that they may produce a false positive in the event that the source and target embeddings are similar to each other, but not good translations of each other. Consider, for example, a source and target pair in which the target is simply a copy of the source. This is clearly not a good translation; nothing has been translated. However, the embeddings would be exactly the same, and thus appear to be a very good match. This exact scenario is easily remedied by the use of a language identification filter, but other instances may be more difficult to root out. For example, a source and target sentence in which the target sentence is a string of literal word-for-word translations of the source sentence. To complement the LASER similarity scores and introduce some measure of fluency we train a language model for both English and Pashto.

4.1 LASER Similarity Scores

The LASER similarity scores provided are produced using the methodology outlined in the WMT19 submission (Chaudhary et al., 2019). A language identification filter is applied, and sentences pairs with an overlap between source and target of greater than 60% are discarded. The similarity scores are based on the cosine similarity between the multilingual sentence embeddings in the learned embedding space, and normalized with a margin using the k nearest neighbors approach.

4.2 Language Model Scores

Language models were trained on the provided clean monolingual data. For the English language model was trained on the Wikipedia corpus with 67,796,935 sentences. The Pashto language model was trained on a concatenation of the CommonCrawl and Wikipedia corpora, with the CommonCrawl oversampled by a factor of 64 to produce a dataset of 9,273,763 sentences. The shuffled datasets were split 90/10 (train/test) with test split into 90/10 (dev/test). The language models were trained using `fairseq` (Ott et al., 2019) with the same settings as the WikiText103 example [1].

The language model, M, was used to produce per-sentence perplexity scores for each of the sentences in the corpus. Where $s = w_1, w_2, ..., w_n$ is a sentence of length n:

$$PPL_M(s) = 2^{-\frac{1}{n}\log P(w_1,w_2,...,w_n)} \quad (1)$$

[1] https://github.com/pytorch/fairseq/blob/master/examples/language_model/README.md

scoring	BLEU (%)
LASER	9.67
LASER + 0.4 PPL_SCORE	9.82
LASER + 0.5 PPL_SCORE	9.81
LASER + 0.6 PPL_SCORE	9.62
LASER + 0.7 PPL_SCORE	9.75
LASER + 0.8 PPL_SCORE	9.88
LASER + 0.9 PPL_SCORE	9.94
LASER + 1.0 PPL_SCORE	9.57

Table 1: Results on development data (training from scratch) for different scaling factors of the PPL_SCORE.

Perplexity scores for both sides (Pashto and English, $H_{ps}(x)$ and $H_{en}(x)$ respectively) are then added together.

$$\begin{aligned}\text{PPL\_SCORE}(x) = PPL_{M_{en}}(s_{en}) \\ + PPL_{M_{ps}}(s_{ps})\end{aligned} \quad (2)$$

4.3 Combining LASER and LM Scores

The language model scores and LASER similarity scores were combined to produce LASER_LM. Both scores were normalised to fall in the range $[0, 1]$ and the PPL_SCORE subtracted from 1.0, such that lower perplexity corresponded to a higher score. Finally, the two scores were added together to produce the final score in the range $[0, 2]$. We experimented with different scaling factors f for the PPL_SCORE.

$$\begin{aligned}\text{LASER\_LM} = \text{LASER} \\ + \text{f} \cdot (1.0 - \text{PPL\_SCORE})\end{aligned} \quad (3)$$

Table 1 shows the range of factors f explored to select the scaling factor used in the final score. Since the BLEU scores produced differed only slightly, we also evaluated the models on some of the provided clean data, randomly selecting 2500 lines (roughly the size of the provided devset) from each of the clean corpora, as well as 2500 lines of a shuffled concatenation (concat) of the clean corpora. Results are shown in table 2. For the most part, they did not vary greatly, and where they did there was no consistent winner across corpora. We choose a factor of 0.5, as the model resulting from these scores generally performed well, and, importantly, performed well on the provided devset.

5 DCCEF_DUP

The dual conditional cross entropy scores produced state-of-the-art performance on the WMT18 shared task on filtering corpora for high-resource languages. However, this method requires two translation models trained in both the forward and backward direction. This presents a challenge in low-resource conditions due to the limited training data available. We find that the model quality can be improved by supplementing the provided clean data with a subsampled set consisting of 1M English tokens of the noisy data, subsampled based on the LASER similarity scores.

5.1 Preprocessing

Sentence pairs in which one or both of the sentences did not match the expected language (English or Pashto) as determined by `fastText` [2] were given a score of 0, effectively removing this pair from consideration. This is a harsh filter, removing around 45% of sentence pairs.

The resulting scores were scaled by the overlap between source and target sentence tokens, producing a sort of non-word token matching score. Note that this does not reward pairs that copy large portions of the source sentence to the target, as these are already removed by the language identification filtering.

5.2 Dual Conditional Cross Entropy Scores

Dual Conditional Cross Entropy Filtering (Junczys-Dowmunt, 2018) was found to be state of the art in the WMT18 high-resource data filtering task (Koehn et al., 2018). The method uses two translation models in the forward and backward direction, which are used to compute crosslingual similarity scores. Given the translation model M, sentence pairs (x, y) from the noisy corpus were force-decoded and a cross-entropy score produced:

$$H_M(y|x) = \frac{1}{|y|}\sum_{t=1}^{|y|} \log p_M(y_t|y_{[1,t-1],x}) \quad (4)$$

Cross-entropy scores for both directions (source-to-target and target-to-source, $H_F(y|x)$ and $H_B(x|y)$ respectively) are then averaged with a penalty on a large difference between the scores to produce the overall score:

$$\begin{aligned}\text{DCCEF}(x, y) = &\frac{H_F(y|x) + H_B(x|y)}{2} \\ &- |H_F(y|x) - H_B(x|y)|\end{aligned} \quad (5)$$

Table 2: Results (BLEU(%)) on subsamples of clean data (training from scratch) for different scaling factors of the PPL_SCORE.

Translation models were trained using `fairseq` (Ott et al., 2019) with the same parameters used in the baseline flores model [3].

We used the provided clean training data to train translation models in both directions, and used these models to produce a dccef score as described above. Initially **only** the dccef scores were used to filter the noisy data and train a system, we did not perform the preprocessing as described in 5.1. The BLEU score produced by this system is shown in 3 under clean.

We then supplemented the clean training data with a subsample of the noisy data and trained translation models in both directions on the augmented data. The subsample of 1 million English tokens and their translations was selected based on the provided LASER similarity score. Again, for this experiment only the dccef scores were used to filter the noisy data, no preprocessing was performed. As shown in Table 3, supplementing the training data with the subsampled set resulted in an overall increase in 3.37 BLEU points.

Finally, we preprocessed the noisy data as described in 5.1 and used both sets of systems (one set trained on clean data, and one set trained on augmented data) to score the preprocessed data. As shown in Table 3, there were further, significant gains, from preprocessing, and the dccef scores from the systems trained on augmented data outperformed the dccef scores from the systems trained on just the clean data. Prepocessing also reduced the gap between the performance of dccef scores produced by systems trained on just the clean data and the performance of dccef scores produced by systems trained on augmented data.

[3] https://github.com/facebookresearch/flores#train-a-baseline-transformer-model

5.3 Duplication Penalty

The scores were scaled by a duplication penalty for duplicate (greater than one) occurrences of either one or both of the target or source sentence of a pair in the corpus as follows:

$$\text{dup\_penalty} = \begin{cases} 1.0 & \text{neither side duplicate} \\ 0.9 & \text{one side duplicate} \\ 0.8 & \text{both sides duplicate} \end{cases} \quad (6)$$

This resulted in a minor improvement in BLEU score on the development data, as seen in Table 3.

6 Results

Various other combinations of the aforementioned scores were explored, and the results are listed in Table 4. Interestingly, the results suggest that the duplication penalty did not improve the LASER_LM score, and combining the LASER_LM and DCCEF_DUP scores did not result in a better BLEU score. However, it should be noted that the differences in BLEU scores resulting from different combinations are generally minor and may not be statistically significant.

None of the filtering methods significantly outperformed the LASER-based method, but the improved dccef filtering method can at least match the LASER-based method when the training data is augmented, and the preprocessing steps and duplication penalty are applied.

7 Conclusion

This paper describes the our submission to the WMT20 Parallel Corpus Filtering Shared Task for low-resource conditions. We find that filtering based on dccef scores can compete with filtering based on LASER similarity scores when the models trained for the dccef scores are augmented with a subsample of the noisy data. This suggests that

training data for H_{en},H_{ps}	scoring method	BLEU (%)

Abstract

The National Research Council of Canada's team submissions to the parallel corpus filtering task at the Fifth Conference on Machine Translation are based on two key components: (1) iteratively refined statistical sentence alignments for extracting sentence pairs from document pairs and (2) a crosslingual semantic textual similarity metric based on a pretrained multilingual language model, XLM-RoBERTa, with bilingual mappings learnt from a minimal amount of clean parallel data for scoring the parallelism of the extracted sentence pairs. The translation quality of the neural machine translation systems trained and fine-tuned on the parallel data extracted by our submissions improved significantly when compared to the organizers' LASER-based baseline, a sentence-embedding method that worked well last year. For re-aligning the sentences in the document pairs (component 1), our statistical approach has outperformed the current state-of-the-art neural approach in this low-resource context.

1 Introduction

The aim of the Fifth Conference on Machine Translation (WMT20) shared task on parallel corpus filtering (Koehn et al., 2020) is essentially the same as the two previous editions (Koehn et al., 2018b, 2019): identifying high-quality sentence pairs in a noisy corpus crawled from the web using ParaCrawl (Koehn et al., 2018a), in order to train machine translation (MT) systems on the clean data.

This year, the low-resource language pairs being tested are Khmer–English (km–en) and Pashto–English (ps–en). Specifically, participating systems must produce a score for each sentence pair in the test corpora indicating the quality of that pair. Then samples containing the top-scoring 5M words are used to train MT systems. While using the filtered parallel data to train a FAIRseq (Ott et al., 2019) neural machine translation (NMT) system remains the same as last year, the organisers are no longer building statistical machine translation (SMT) systems as part of the task evaluation. Instead, as an alternative evaluation, the filtered parallel corpus is used to fine-tune an MBART (Liu et al., 2020) pretrained NMT system. Participants were ranked based on the performance of these MT systems on a test set of Wikipedia translations (Guzmán et al., 2019), as measured by BLEU (Papineni et al., 2002). A few small sources of parallel data, covering different domains, were provided for each of the two low-resource languages. Much larger monolingual corpora were also provided for each language (en, km and ps). In addition to the task of computing quality scores for the purpose of filtering, there is also a sub-task of re-aligning the sentence pairs from the original crawled document pairs.

Cleanliness or quality of parallel corpora for MT systems is affected by a wide range of factors, e.g., the parallelism of the sentence pairs, the fluency of the sentences in the output language, etc. Previous work (Goutte et al., 2012; Simard, 2014) showed that different types of errors in the parallel training data degrade MT quality in different ways. Cross-lingual semantic textual similarity is one of the most important properties of high-quality sentence pairs. Lo et al. (2016) scored cross-lingual semantic textual similarity in two ways, either using a semantic MT quality estimation metric, or by first translating one of the sentences using MT, and then comparing the result to the other sentence, using a semantic MT evaluation metric. At the WMT18 parallel corpus filtering task, Lo et al. (2018)'s supervised submissions were developed for the same MT evaluation pipeline using a new semantic MT metric, YiSi-1 (Lo, 2019) (see also section 2.3). At the WMT19 parallel corpus filtering task, Bernier-

Proceedings of the 5th Conference on Machine Translation (WMT), pages 972–978

Colborne and Lo (2019) exploited the quality estimation metric YiSi-2 using bilingual word embeddings learnt in a supervised manner (Luong et al., 2015) from clean parallel training data or a weakly supervised manner (Artetxe et al., 2016) from bilingual dictionary. Lo and Simard (2019) further showed that using YiSi-2 with multilingual BERT (Devlin et al., 2019) on fully unsupervised parallel corpus filtering (i.e. without access of any parallel training data) achieved similar results to those in Bernier-Colborne and Lo (2019).

This year, the National Research Council of Canada (NRC) team submitted one system to the parallel corpus filtering task and one to the alignment task. The two systems share the same components in scoring the parallelism of the noisy sentence pairs, i.e., the pre-filtering rules and the quality estimation metric YiSi-2. For the parallel corpus aligning task, we use an iterative statistical alignment method to align sentences from the given document pairs before passing the aligned sentences to the scoring pipeline.

Our internal results show that MT systems trained on pre-aligned sentences filtered by our scoring pipeline outperform those trained on the organizers' LASER-based baseline (Chaudhary et al., 2019) by 0.2–1.4 BLEU. Training MT systems on re-aligned sentences using our iterative statistical alignment method achieve further gains of 0.3–1.8 BLEU.

2 System architecture

There are a wide range of factors that determine whether a sentence pair is good for training MT systems. Some of the more important properties of a good training corpus include:

- High parallelism in the sentence pairs, which affects translation adequacy.
- High fluency and grammaticality, especially for sentences in the output language, which affect translation fluency.
- High vocabulary coverage, especially in the input language, which helps make the translation system more robust.
- High variety of sentence lengths, which should also improve robustness.

In previous years, we explicitly tried to maximize all four of these properties, but this year we focused only on the first two in the scoring presented in section 2.3 below.

2.1 Iterative statistical sentence alignment

Our iterative statistical sentence alignment method as detailed in Joanis et al. (2020) uses `ssal`, a reimplementation and extension of Moore (2002) which is part of the Portage statistical machine translation toolkit (Larkin et al., 2010).

First, we train an IBM-HMM model (Och and Ney, 2003) on the clean parallel training data and the subsampled noisy corpora (see Table 1 for statistics) and use it to align paragraphs in the given document pairs, as Moore (2002) does. The subsampled noisy corpora are those obtained by applying our filtering baseline as described in sections 2.2 and 2.3 (and denoted as "nrc.baseline" in table 2). Then, we segment the paragraphs in both languages into sentences using the Portage sentence splitter. Finally, we align sentences within aligned paragraphs using the IBM model again. In this process, both the data used in training the IBM-HMM model and the noisy document pairs for alignment are punctuation tokenized using the Portage tokenizer.

In past work on sentence alignment (Joanis et al. (2020) and other unpublished experiments), we have found that first aligning paragraphs and then aligning sentences within aligned paragraphs outperforms approaches that align sentences without paying attention to paragraph boundaries.

2.2 Initial filtering

The pre-filtering steps of our submissions are mostly the same as those in Bernier-Colborne and Lo (2019). We remove:

1. duplicates after masking email, web addresses and numbers,
2. sentence pairs with a majority of number mismatches,
3. sentence pairs with either side in the wrong language according to the `pyCLD2` language detector[1],
4. sentence pairs where over half of the source sentence is non-alphabetical or target language characters, and
5. sentence pairs where over half of the target sentence is non-alphabetical characters.

An additional pre-filtering rule included in this year's submissions is the removal of pairs where over 50% of the target English sentence is directly

copying from the source Khmer or Pashto sentence.

2.3 Sentence pair scoring

The core of our sentence pair scoring component is the semantic MT quality estimation metric, YiSi-2. YiSi (Lo, 2019) is a unified semantic MT quality evaluation and estimation metric for languages with different levels of available resources. YiSi-1 measures the similarity between a machine translation and human references by aggregating weighted distributional (lexical) semantic similarities, and optionally incorporating shallow semantic structures. YiSi-2 is the bilingual, reference-less version, which uses bilingual word embeddings to evaluate cross-lingual lexical semantic similarity between the input and MT output or, in this task, between the source and target sentences.

YiSi-2 relies on a crosslingal language representation to evaluate the crosslingual lexical semantic similarity. Previously, it used pre-trained multilingual BERT (Devlin et al., 2019) for this purpose. In this work, we instead experiment with XLM-RoBERTa (Conneau et al., 2020) because (1) at the time this work was done, it was the only pre-trained multilingual language encoder that covers both Khmer, Pashto and English; and (2) it shows better performance with lower-resource languages than BERT.

As suggested by Devlin et al. (2019); Peters et al. (2018); Zhang et al. (2020), we experiment with using contextual embeddings extracted from different layers of the multilingual language encoder to find out the layer that best represents the semantic space of the language.

YiSi is semantic oriented. In the past, we noticed that YiSi-based scoring functions failed to filter out sentence pairs with disfluent target text. Following Zhao et al. (2020), we experiment with improving the sentence pair scoring function by linearly combining YiSi score with the language model (LM) scores of the target text obtained from the multilingual language model used in YiSi. However, instead of using an additional pretrained language model—GPT-2 (Radford et al., 2019)—as in Zhao et al. (2020), we use the left-to-right LM scores obtained from XLM-RoBERTa while computing the crosslingual lexical semantic similarity. The advantages of using the same pretrained model for computing the crosslingual lexical semantic similarity and the language model scores are 1) it costs less in both memory and computation; 2) it is more portable to languages other than English. We combined the LM scores in the probability domain linearly with the semantic similarity scores with a weight of 0.1 assigned to the LM scores.

In the WMT19 metrics shared task (Ma et al., 2019), we saw a very significant performance degradation between YiSi-1 and YiSi-2. This suggests that current multilingual language models construct a shared multilingual space in an unsupervised manner without any direct bilingual signal, in which representations of context in the same language are likely to cluster together in part of the subspace and there is a language segregation in the shared multilingual space. Inspired by Artetxe et al. (2016) and Zhao et al. (2020), we sample 5k clean sentence pairs and use the token pairs aligned by maximum alignment of their semantic similarity to train a cross-lingual linear projection that would transform the source embeddings into the target embeddings subspace.

Lo and Larkin (2020) provide a detailed correlation analysis of YiSi-2 with all the improvements mentioned above and human judgment on

MT reference-less evaluation.

3 Experiments and results

We used the software provided by the task organizers to extract the 5M-word samples from the original test corpora according to the scores generated by each alignment and/or filtering system. We then trained a FAIRseq MT system or fine-tuned an MBART pretrained NMT using the extracted subsamples. The MT systems were then evaluated on the official dev set ("dev-test").

We exhaustively experimented with the last few layers of both XLM-RoBERTa$_{base}$ and XLM-RoBERTa$_{large}$ in order to find out the model and layer best representing crosslingual semantic similarity. Figure 1 shows the plots of the change in BLEU scores of each MT system using the embeddings extracted from the n^{th} layer, counting from the last, of the multilingual LM for evaluating crosslingual lexical semantic similarity. In general, we see a trend of rising performance as we roll back from the last layer. The performance peaks at some point and starts to fall when we roll back too far from the end. For XLM-RoBERTa$_{base}$, the peak performance of the MT systems is achieved by the 3$^{\text{rd}}$ or 4$^{\text{th}}$ last layer (out of 12 layers). For XLM-RoBERTa$_{large}$, the peak performance of the MT systems is achieved by the 8$^{\text{th}}$ last layer (out of 24 layers). The peak performance of MT systems trained on sentences filtered by XLM-RoBERTa$_{large}$ based YiSi-2 is better than that by XLM-RoBERTa$_{base}$ based YiSi-2.

re-aligning and filtering					
iterative alignment + nrc.filtering	nrc.alignment	***8.82***	11.17	***11.73***	***13.21***

Table 2: BLEU scores of selected systems. The two final submitted systems are labelled nrc.filtering and nrc.alignment.

Table 2 shows the results of the experiments described in section 2.3. First, we show an improved version of the organizers' baseline by simply adding our initial filtering rules. This shows that our initial filtering rules are able to catch bad parallel sentences which are hard to filter by an embedding-based filtering system.

Next, we see that using YiSi-2 with XLM-RoBERTa$_{large}$'s 8th last layer as parallelism scoring function outperforms the LASER baseline by 0.1–0.9 BLEU in different translation directions and MT architectures. This is our "nrc.baseline" system, and the baseline used for filtering the noisy corpus in training the IBM-HMM alignment model for the "nrc.alignment" system. Adding the LM score to the scoring function shows small improvements. Learning the cross-lingual linear projection matrix to transform the source embeddings in the target language subspace shows more improvements overall. This is our "nrc.filtering" submission to the parallel corpus filtering task.

At last, we show that using our iterative statistical alignment method to redo the alignment of sentences from the given document pairs improves the translation quality of the resulting MT systems significantly. This is our "nrc.alignment" submission to the parallel corpus filtering task.

4 Conclusion and Future Work

In this paper, we presented the NRC's two submissions to the WMT20 Parallel Corpus Filtering and Alignment for Low-Resource Conditions task. Our experiments show that YiSi-2 is a scoring function of parallelism that is very competitive, and that a statistical sentence alignment method is still able to provide better alignment results than neural ones in low resource situations. Further analysis is required to understand the characteristics of the sentence pairs aligned by the baseline vecalign and our iterative statistical sentence alignment and how the latter achieves better translation quality for the trained MT systems.

It is worth highlighting that in this task, as well as in our Inuktitut–English corpus alignment work (Joanis et al., 2020), a well-tuned statistical sentence-alignment system outperformed a state-of-the-art neural one. We hypothesise that this is a low-resource effect, but further work is still needed to explore the best low-resource corpus alignment methods. In particular, we intend to integrate YiSi-2 into our sentence aligner to test whether it's our iterative alignment methodology that makes the difference or the fact that the underlying scoring function is statistical (we use IBM-HMM models for sentence pair scoring in our aligner). It's possible that the statistical approach might continue to win here, because in the low-resource context there might not be enough training data to tune the orders of magnitude more parameters of the neural models; a counter-argument is that YiSi-2 did better on the scoring task than statistical scoring functions. Our future work will explore the trade-offs between these two approaches, and consider hybrid methods.

Acknowledgements

We thank Samuel Larkin and Marc Tessier for their help in setting up the FAIRseq and MBART baselines using the LASER scores; and Patrick Littell for discussion and feedback on the Pashto test set. We also thank the reviewers for their comments and suggestions, and Roland Kuhn for his comments and feedback on the paper.

Abstract

This paper describes the Alibaba Machine Translation Group submissions to the WMT 2020 Shared Task on Parallel Corpus Filtering and Alignment. In the filtering task, three main methods are applied to evaluate the quality of the parallel corpus, i.e. a) Dual Bilingual GPT-2 model, b) Dual Conditional Cross-Entropy Model and c) IBM word alignment model. The scores of these models are combined by using a positive-unlabeled (PU) learning model and a brute-force search to obtain additional gains. Besides, a few simple but efficient rules are adopted to evaluate the quality and the diversity of the corpus. In the alignment-filtering task, the extraction pipeline of bilingual sentence pairs includes the following steps: bilingual lexicon mining, language identification, sentence segmentation and sentence alignment. The final result shows that, in both filtering and alignment tasks, our system significantly outperforms the LASER-based system.

1 Introduction

The parallel corpus is an essential resource for building a high quality machine translation(MT) system. It has been shown that, the higher the corpus quality, the better the performance of a MT system(Koehn and Knowles, 2017; Khayrallah and Koehn, 2018). Many successful machine translation systems are built on the corpus crawled from the web. In practice, this kind of parallel corpus may be very noisy. The task of Parallel Corpus Filtering is aimed at tackling the problem of cleaning noisy parallel corpora.

We form the bilingual sentences quality in the following aspects. Firstly, a *high-quality* parallel sentence pair(also called bitext) should have the property that its target sentence precisely translates the source sentence, and vice versa. In this task, we attempt to quantify the translation accuracy (also called bilingual score) of bilingual sentence pairs. Secondly, the monolingual quality of the target and source sentences of a parallel corpus should also be considered. In our system, we evaluate the monolingual quality (also called monolingual score) of a target sentence due to its importance for the MT procedure. Finally, the bilingual and monolingual scores are combined to evaluate bilingual sentence pairs and filter out the ones with low quality.

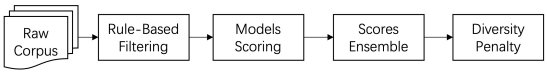

Figure 1: Framework of parallel corpus filtering

The paper is structured as follows. Section 2 describes our methods which are used in the parallel corpus filtering. In Section 3, we briefly outline the pipeline of parallel sentence extraction. Section 4 specifies the experiments and results as well as the dataset for building model-based methods. Conclusions are drawn in Section 5.

2 Parallel Corpus Filtering Methods

Figure 1 shows the framework of parallel corpus filtering. The raw parallel corpus is firstly filtered by heuristic rules so that the very noisy sentence pairs will be removed. Then, the bilingual & monolingual models are built to score all the remaining sentence pairs. By using an ensemble model, the partial scores of each sentence pair are combined to a single quality score.

2.1 Rule-based Filtering

A series of heuristic rules(Lu et al., 2018) are applied to filter low quality sentence pairs. They are simple, (almost) language independent but efficient, which are described below.

Proceedings of the 5th Conference on Machine Translation (WMT), pages 979–984
Online, November 19–20, 2020.

Monolingual Rules

- The length of the sentence which is too short (≤ 2 tokens) or too long (> 200 tokens) will be dropped. In our system, sentences(English, Khmer and Pashto) are tokenized by SentencePiece[1].

- The ratio of the valid tokens count to the length of the sentence. Here, valid tokens are the ones which contain the letters in the corresponding language. For example, a valid token in English should contain English letters. In our system, the sentence is filtered out if its valid-tokens ratio is less than 0.2.

- Language filtering. For the Pashto-English parallel corpus, the languages of source and target sentences should be Pashto and English. We detect the language of a sentence by using a language detection tool we developed[2]. A sentence pair is dropped when its source language and target language are not Pashto and English, respectively.

Bilingual Rules

- The length ratio of a source sentence to a target sentence. The sentence length is calculated by the number of sentencepiece tokens. In our system, the ratio is set between 0.2 and 5.0 for both language pairs.

- The edit distance between the source token sequence and the target token sequence. A small edit distance indicates that the source and target sentences are very similar, which harms the performance of the NMT system a lot (Khayrallah and Koehn, 2018).

- The consistency of special tokens (Taghipour et al., 2010). For example, the high-quality sentence pairs should contain the same email address in both source and target sentences (if exists). In this task, special tokens are email addresses, URLs, and big Arabic numbers.

2.2 Dual Bilingual GPT-2 Model

Inspired by the *Cross-lingual Language Model Pretraining* work of (Lample and Conneau, 2019), we propose a Translation Language Model(called Bilingual GPT-2 model) based on the GPT-2 model(Radford et al., 2019). As illustrated in Figure 2, the Bilingual GPT-2 model is trained with both monolingual and parallel sentences. For parallel sentence pairs, we concatenate the source and target sides to obtain a long sentence and then feed it to the model. For monolingual sentences, we convert them to *fake sentences pairs* by assigning the corresponding side sentence with a unique token. For example, when an English sentence "Hello word." is used in the English-Khmer bilingual GPT-2 model training, a fake sentence pair, ("Hello word", "<KM>"), will be used. Here, the English sentence is the source and "<KM>" is the target. While training, a large number of fake bilingual corpora are firstly used to *pre-train* the model. Then, the real clean parallel sentence pairs are used to *fine-tune* the model. In this task, we trained two Bilingual GPT-2 models for each language pair, i.e., source-to-target and target-to-source models. The two translation quality scores from the Dual Bilingual GPT-2 model are given precisely by:

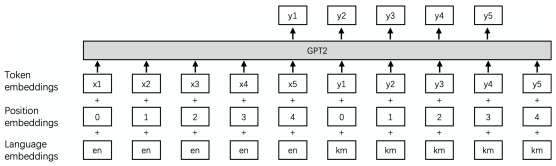

Figure 2: Bilingual GPT-2 model structure

$$score_1(x,y) = \frac{1}{2}\Big(\sum_{t\in|y|} \log p_{s2t}(y_t) + \sum_{t\in|x|} \log p_{t2s}(x_t)\Big) \quad (1)$$

$$score_2(x,y) = \frac{1}{2}\Big(\sum_{t\in|y|} \log p_{s2t}(y_t) - \log p_{t2s}(y_t) + \sum_{t\in|x|} \log p_{t2s}(x_t) - \log p_{s2t}(x_t)\Big) \quad (2)$$

In Equation (1) and (2), x and y are the source and target sentences. $logp_{s2t}(y_t)$ represents the cross-entropy loss of the target side token y_t, which is obtained by the source-to-target model. $\log p_{t2s}(x_t)$ represents the cross-entropy loss of the source side token x_t, which is obtained from the target-to-source model.

We don't use the BERT model here, as it is hard for computing the cross-entropy loss efficiently.

[1] https://github.com/google/sentencepiece

[2] This tool is similar to Google's CLD2: https://github.com/CLD2Owners/cld2

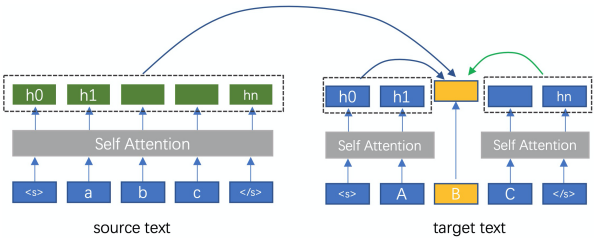

Figure 3: Optimized cross entropy model (source-to-target)

2.3 Dual Conditional Cross-Entropy Model

The dual conditional cross-entropy model(Junczys-Dowmunt, 2018) has been proven effective in parallel corpus filtering, which uses a combination of forward and backward models to compute a force-decoding score. In our system, the model is optimized to better evaluate the quality of the parallel sentences in low-resource languages.

Specifically, Figure 3 shows the structure of our model. Each token in a target side sentence is predicted by its left and right context and the source text. Hence, the cross-entropy score of a sentence pair is given below:

$$H_M(y|x) = \frac{1}{|y|} \sum_{t \in |y|} \log p_M(y_t|x, y_{<t}, y_{>t})$$

The final bilingual quality score combines the source to target and target to source cross-entropy scores as below:

$$score(x,y) = \frac{1}{2}(H_{Fwd}(y|x) + H_{Bck}(x|y)) + |H_{Fwd}(y|x) + H_{Bck}(x|y)|$$

As shown in Figure 3, the source sentence and target context are encoded by two 12-layer transformer models with hidden size 768. In fact, the target side model can be regarded as a bidirectional GPT-2 model. In our system, the source and target side transformer models are pre-trained by using large amount of monolingual data. Then, the models are fine-tuned by clean bilingual sentences pairs.

2.4 IBM Word Alignment Model

The word alignment model can be used for evaluating the translation quality of bilingual sentence pairs (Khadivi and Ney, 2005; Taghipour et al., 2010; Ambati, 2011). Inspired by the work of (Khadivi and Ney, 2005), we simplify the original algorithm, and the translation score of sentence pairs is given below:

$$score(s,t) = \frac{1}{|s|} \sum_{s_i,t_j \in a_{s2t}} \log p(t_j|s_i) + \frac{1}{|t|} \sum_{s_i,t_j \in a_{t2s}} \log p(s_i|t_j) \quad (3)$$

In Equation (3), s and t represent the source and target sentences respectively, $p(w_1|w_2)$ indicates the word translation probability, and a_{s2t} indicates the source words to target words alignment.

In this task, by using the *fast_align* toolkit (Dyer et al., 2013), the word alignment model is trained on a clean parallel corpus as described in Section 4.1 to get the forward and reverse word translation probability tables. This model is also called alignment scoring model.

2.5 GPT-2 Language Model

In this task, GPT-2 language model is applied to compute the monolingual scores of source and target sentences. We train GPT-2 models for each language by using the *HuggingFace Transformers* toolkit (Wolf et al., 2019) with the monolingual data provided by the task organizers. The training data is cleaned by the rules described in the Section 2.1. The configuration of the GPT-2 model is also the same with the *GPT2-large model* described in the work of (Radford et al., 2019).

2.6 Ensemble

Each sentence pair in the noisy parallel corpus is scored by each of the models described above. As a result, each sentence pair would obtain a few partial scores. We need a single score based on the partial scores to rank the sentence pairs.

At first, we turn the scores from each model to the values between 0 and 1. Specifically, the scores are normalized with the method described in (Junczys-Dowmunt, 2018), which is based on the entropy information.

Then, a single score $f(x,y)$ is produced as the product of partial scores $f_i(x,y)$. Since the different importance of the partial scores, the lower boundary value of the scores is represented as θ, where $0 \leq \theta \leq 1$, which results in a new normalization range $[\theta, 1]$. The more important the model is, the closer to 0 the θ is. It means that the scores from this model could distribute from 0 to 1, which

would affect a lot on the final score. On the contrary, when we set θ close to 1, the model has minor impact on the final score whatever its distribution is. Hence, the single score is given by:

$$f(x,y) = \prod_i f_i(x,y), f_i(x,y) \in [\theta_i, 1] \quad (4)$$

We applied the brute-force search to find the best θs for the models. Compared to the pure production of the partial scores, our method has improved 0.5% - 1.0% BLEU score(Papineni et al., 2002).

In addition, the ensemble could also be treated as a Positive-Unlabeled classification task (Chaudhary et al., 2019). We use the officially released high quality data and the sentence pairs which are ranked top by our models mentioned above as the positive samples. Meanwhile, the sentence pairs from the noisy parallel corpus are treated as the unlabeled samples. As a result, the PU classification based on the random forest models has contributed 0.1% - 0.2% improvement on the development data.

In our final submissions, the brute-force search method and PU-classification are used in Khmer-English and Pashto-English filtering tasks respectively.

3 Pipeline of Parallel Corpus Extraction

Bilingual Lexicon Extraction. In the first step, by using the word alignment model, parallel token pairs are extracted from the clean parallel corpus. Specifically, after tokenization, the parallel corpus is fed to the fast align toolkit to obtain the mutual translation probabilities dictionary. We then extract the token pairs with forward and backward translation probabilities higher than 0. The bilingual lexicon (i.e., the collection of parallel token pairs) will iteratively be updated after more bitexts are mined, since the lexicon is the cornerstone of bitexts mined from aligned documents which is described below.

Language Identification. The second step is to identify the language of each document by using a language detection tool we developed. In this way, a document pair will be discarded if its detection results do not match the expected languages.

Sentence Segmentation. This step is to split sentences in documents with rules or models. A few rules based on end-of-sentence punctuations are used to split sentences of language Pashto and Khmer. For English sentence segmentation, a segmentation model is built via nltk toolkit[3].

Language	Sentences	English Words
Khmer-English	270K	4.2M
Pashto-English	106k	1.9M

Table 1: Clean bitexts used in bilingual models training

Sentence Alignment. In this step, a dynamic programming framework based on bilingual lexicon (Ma, 2006) is built to mine parallel sentence pairs.

Corpus Filtering. Finally, the extracted bitexts are cleaned by using the methods described in section 2. And as mentioned above, we mix the new mined bitexts with the provided bitexts from WMT2020 to iteratively run the fast_align model to update bilingual lexicon.

4 Experiments and Results

In this section, we specify the experimental settings and results in the corpus filtering and alignment task.

4.1 Corpora and Settings

The selection data pool[4] (which we called noisy dataset) is provided by *WMT20 Corpus Filtering and Alignment Task*. It contains 1.02 million sentences pairs of Pashto-English corpus and 4.17 million sentences pairs of Khmer-English corpus. These parallel corpora are very noisy. The task's participants are asked to sub-select sentence pairs that amount to 5 million English words for each of the noisy parallel sets. The quality of the resulting subsets is determined by the BLEU scores of a neural machine translation system[5] trained on selected data. In our NMT experiments, we use the NMT configuration that is provided by the task organizers[6] as well as the development and test sets.

In addition, organisers provide the permissible third-party sources of parallel corpora, which we called "official parallel data". Additional monolingual corpora are also provided for English, Khmer and Pashto languages. For sentence pair alignment task, the organisers also provide the document pairs

Table 2: Main results for corpus filtering and alignment task

in which the participants can extract bilingual sentence pairs.

In Section 2, we introduced 3 sub-models for translation quality scoring, i.e. Dual Bilingual GPT-2 Model, Dual Conditional Cross-Entropy and IBM Word Alignment Model. These models can be trained with the monolingual and clean parallel corpus. In particular, the clean parallel data is more important in training. Unfortunately, both Khmer-English and Pashto-English are low-resource language pairs and lack parallel corpus. Therefore, in order to expand the clean parallel dataset, the high quality sentence pairs are selected/extracted from the noisy dataset or the parallel document pairs by using an iterative process in our filtering system. Specifically, the corpus filtering models are initially trained by using the official parallel data. Then, these models are used to estimate the quality of the sentence pairs in the noisy dataset and parallel documents. Finally, by applying some rules and strict threshold value, the high quality sentence pairs are selected and combined with official parallel data to train the new version of filtering models. The process described above was repeated 3 times and achieved larger clean parallel corpora as detailed in Table 1.

For text preprocessing, we built two joint SentencePiece models for Khmer-English and Pashto-English respectively with the 60k vocabulary size. Then, monolingual and bilingual texts are tokenized by the corresponding SentencePiece models.

4.2 Experimental Results

Our main results are shown in Table 2. All NMT experiments were done in the same environment with 2 GPUs for normal training (i.e., NMT training from scratch) and 1 GPU for MBART-based fine-tuning[7]. The LASER scores provided by the organisers were used as baseline scores, which achieved reasonable results in both normal training and MBART-based fine-tuning. Our rules proposed above were firstly used to filter very noisy sentence pairs and achieved a slightly better performance. Then, the 3 main bitexts scoring models were combined with rules respectively to test their effectiveness in experiments. We found that, the IBM word alignment model was reliable in most cases and Dual Bilingual GPT-2 model slightly outperformed the Dual Conditional Cross-Entropy model. Finally, the ensemble model obtained the highest BLEU scores in the filtering task.

In the task of sentence pairs alignment, we only submitted the results of Pashto-English. While extracting sentence pairs, 13,976 bilingual word pairs were firstly obtained from the clean parallel corpus. As a result, we mined 723,414 sentence pairs from 45,307 document pairs and achieved an improvement of 0.5 BLEU score.

5 Conclusions

In this paper, we present our corpus filtering system for the *WMT 2020 Corpus Filtering Task*. In our system, Dual Bilingual GPT-2 model, Dual Conditional Cross-Entropy model and IBM word alignment model are combined to filter the noisy parallel corpus. Besides, a parallel sentence pairs extraction system is built to re-align the bilingual sentences. The experiments show that, compared

[7]The MBART pre-trained models were provided by the organizers and described here, http://www.statmt.org/wmt20/parallel-corpus-filtering.html.

to the baseline system, our filtering and extraction system achieve much better results.

Abstract

In this paper, we describe our submissions to the WMT20 shared task on parallel corpus filtering and alignment for low-resource conditions. The task requires the participants to align potential parallel sentence pairs out of the given document pairs, and score them so that low-quality pairs can be filtered. Our system, Volctrans, is made of two modules, i.e., a mining module and a scoring module. Based on the word alignment model, the mining module adopts an iterative mining strategy to extract latent parallel sentences. In the scoring module, an XLM-based scorer provides scores, followed by reranking mechanisms and ensemble. Our submissions outperform the baseline by 3.x/2.x and 2.x/2.x for km-en and ps-en on From Scratch/Fine-Tune conditions.

1 Introduction

With the rapid development of machine translation, especially **N**eural **M**achine **Translation** (NMT) (Vaswani et al., 2017; Ott et al., 2018; Zhu et al., 2020), parallel corpus in high quality and large quantity is in urgent demand. These parallel corpora can be used to train and build robust machine translation models. However, for some language pairs on low-resource conditions, few parallel resources are available. Since it is much easier to obtain quantities of monolingual data, it may help if we can extract parallel sentences from monolingual data through alignment and filtering.

The WMT19 shared task on parallel corpus filtering for low-resource conditions (Koehn et al., 2019) provides noisy parallel corpora in Sinhala-English and Nepali-Englis crawled from the web. Participants are asked to score sentence pairs so that low-quality sentences are filtered. In this year, the WMT20 shared task on parallel Corpus filtering and alignment for low-resource conditions is very similar, except that the language pairs become Khmer-English and Pashto-English, and the provided raw data are documents in pair, which require sentence-level alignment. Besides, no data in similar languages are provided for this year.

The participants are required to align sentences within documents in different languages and provide a score for each sentence pair. To evaluate the quality of the extracted sentence pairs, they are subsampled to 5 million English words and used to train a neural machine translation model. Finally, the BLEU score of the machine translation system is used to reflect the quality of the sentence pairs.

In this paper, we propose the Volctrans filtering system, which consists of a **mining module** and a **scoring module**. First, the mining module extracts and aligns potential parallel sentence pairs within documents in different languages. In particular, we introduce an iterative mining strategy to boost mining performance. We keep adding newly aligned high-quality parallel sentences to train the word alignment model, which is essential for the mining module. Second, the scoring module is based on XLM (Conneau and Lample, 2019), and responsible for providing scores for each sentence pair. Several reranking mechanisms are also used in this module. We conduct experiments to tune the hyper-parameters for the best filtering performance, and four systems are ensembled to achieve the final results.

2 System Architecture

2.1 Data Introduction

In detail, as is shown in Table 1, the WMT20 shared task provides:

- Document pairs, including $391,250$ Khmer-English and $45,312$ Pashto-English document pairs;
- Sentence-aligned corpora extracted from the

Proceedings of the 5th Conference on Machine Translation (WMT), pages 983–990
Online, November 19–20, 2020.

above document pairs, using Hunalign (DBL, 2008) and LASER (Artetxe and Schwenk, 2019), including $4,169,574$ Khmer-English and $1,022,883$ Pashto-English sentence pairs;

- Parallel data which can be used to build filtering and alignment system, including $290,051$ Khmer-English and $123,198$ Pashto-English parallel sentences;
- Monolingual data, including approximately 1.9 billion English, 14.0 million Khmer, and 6.6 million Pashto sentences.

Table 1: Statistics of Provided Data Scale

	en-km	en-ps
Document Pairs	391K	45K
Extracted Sentence Pairs	4.2M	1.0M
Parallel Sentences	290K	123K

2.2 Mining Module

Besides the given aligned sentences, we believe that there are still more potential parallel sentences that can be mined. Thus we choose to extract our own set of sentence pairs from the provided document pairs, and design a mining module aiming to gather as many parallel sentence candidates as possible. We then elaborate on our mining procedure and mining module, shown in Figure 1, in detail.

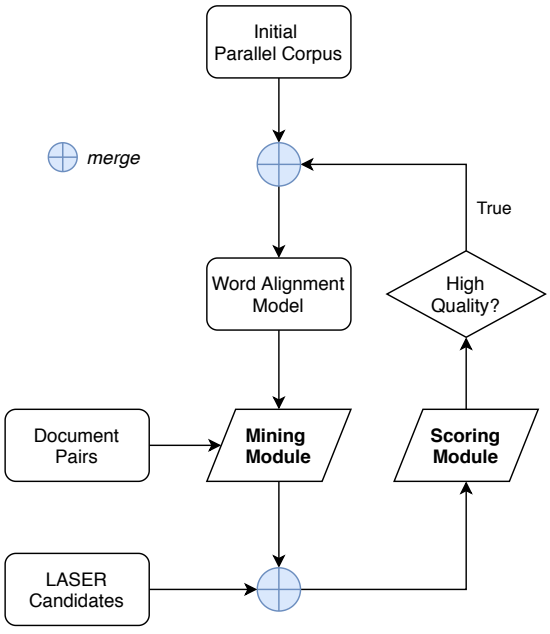

Figure 1: Mining Procedure

2.2.1 Word Alignment

We trained the word alignment model on the provided clean parallel corpus by using the *fast-align* toolkit (Dyer et al., 2013), and get the forward and reverse word translation probability tables. It's worth mentioning that both of Pashto and Khmer corpus are tokenized before word alignment model training for accuracy consideration. We separate Pashto words by moses tokenizer[1]. For Khmer, we use the character (\u200B in Unicode) as separator when it's available and otherwise use a dictionary-based tokenizer by maximizing the word sequence probability.

2.2.2 Mining Parallel Sentences

This step is operated by our mining module. With the bilingual word translation probability tables, the mining module evaluates the translation quality of bilingual sentence pairs by YiSi-2 (Lo, 2019), which involves both lexical weight and lexical similarity. The Document pairs are first segmented on each language side using Polyglot [2]. This initial segmentation is represented as:

$$e = \overline{e}_1 \overline{e}_2 \cdots \overline{e}_a = \overline{e}_1^a \quad (1)$$

$$f = \overline{f}_1 \overline{f}_2 \cdots \overline{f}_b = \overline{f}_1^b \quad (2)$$

where $\overline{e}_k$ ($\overline{f}_k$) is a segment of consecutive words of document e (f). Then we compute the sentence similarity (translation quality) by iteration from the initial segment ($\overline{e}_1$, $\overline{f}_1$). If the similarity reaches the preset threshold for ($\overline{e}_i$, $\overline{f}_j$), we pick the segment pair as parallel sentence candidate, and continue the computation from ($\overline{e}_{i+1}$, $\overline{f}_{j+1}$).

We notice that the inconsistency of segmentation in the document pairs can lead to the results: a sentence in one language contains information only part of a sentence in the other language, or two sentences (in different languages) both contain part of their information in common. These resulting sentence pairs may have low similarity scores.

In order to alleviate this problem, we also incorporate a parallel segmentation method in our mining module. We follow the basic idea proposed in (Nevado et al., 2003) where the parallel segmentation finding problem is treated as an optimization problem and a dynamic programming scheme is

[1] https://github.com/moses-smt/mosesdecoder/blob/master/scripts/tokenizer/tokenizer.perl

[2] https://github.com/aboSamoor/polyglot

used to search for the best segmentation. We then briefly introduce our method. [3]

After obtaining the monolingual initial segmentation $(\overline{e}_1^a, \overline{f}_1^b)$, a parallel segmentation is represented as:

$$s \equiv ([\overline{e}_1^{k_1}, \overline{f}_1^{j_1}], [\overline{e}_{k_1+1}^{k_2}, \overline{f}_{j_1+1}^{j_2}], \cdots, [\overline{e}_{k_{|s|-1}+1}^{k_{|s|}}, \overline{f}_{j_{|s|-1}+1}^{j_{|s|}}]) \quad (3)$$

where $|s|$ is the number of segments for the parallel segmentation s and $\overline{e}_{i_1}^{i_2}$ ($\overline{f}_{i_1}^{i_2}$) are consecutive segments $\overline{e}_{i_1}\overline{e}_{i_1+1}\cdots\overline{e}_{i_2}$ ($\overline{f}_{i_1}\overline{f}_{i_1+1}\cdots\overline{f}_{i_2}$). In this setting, all initial segments will be included in the parallel segmentation, and the order of the initial segments cannot be inverse. Therefore, the alignment is monotone.

Then we search for the best parallel segmentation using the objective function:

$$\max_{S \in s} C \cdot \prod_{n=1}^{|s|} P(\overline{f}_{j_{n-1}+1}^{j_n} | \overline{e}_{k_{n-1}+1}^{k_n}) \quad (4)$$

where $P(\overline{f}_{j_{n-1}+1}^{j_n} | \overline{e}_{k_{n-1}+1}^{k_n})$ is the translation quality of the pair $(\overline{f}_{j_{n-1}+1}^{j_n}, \overline{e}_{k_{n-1}+1}^{k_n})$.

Next, we use a dynamic programming algorithm to compute the best segmentation S where we have a restriction that no more than 3 initial segments can be joined.

Finally, this set of parallel segments are combined with the set of the extracted initial segment pairs through global deduplication to serve as the output of our mining module.

It is worth noting that the sequence can be very long in the process of translation quality computation because several segments can be joined together. Therefore, while computing the similarity of a segment pair, our method based on word translation probability tables can be more time-efficient than LASER, as LASER is based on sentence embeddings and can be very slow when its LSTM encoder is fed with long sequence. Thus we do not consider using LASER to compute translation quality in our mining procedure.

2.2.3 Iterative Mining Strategy

The quantity and quality of the mined data are basically dependent on the word alignment model. Besides, more high-quality parallel corpus is used, the word alignment model would be more accurate and robust. Therefore, we propose an iterative mining strategy. For the first time, all the provided parallel data by the task are used to train the word alignment model. But we keep mining data for several times. We iteratively add new high-quality sentence pairs to the parallel corpus and train the word alignment model again to improve the word translation probability tables, thus boosting the mining cycle.

2.3 Scoring Module

The scoring module consists of three parts. First, we make use of both the parallel and monolingual data to train an XLM-based classifier to score each sentence pair. Secondly, different reranking mechanisms are used to adjust the scores. Finally, we ensemble four different models to improve the performance of our systems.

2.3.1 XLM-based Scorer

Recently, pre-trained transformer-based models play an important role in a variety of NLP tasks, such as question answering, relation extraction, etc.. Pre-trained models are often trained from scratch with self-supervised objective, and then fine-tuned to adapt to the downstream tasks. In our system, we choose the XLM (Conneau and Lample, 2019) as our main model. The reason are as follows: a) Similar to BERT (Devlin et al., 2019; Yang et al., 2019), XLM has **M**asked **L**anguage **M**odel (MLM) objective, which enables us to make the most use of the provided monolingual corpora; b) XLM also has **T**ranslation **L**anguage **M**odel (TLM) objective. Taking two parallel sentences as input, it predicts the randomly masked tokens. In this way, cross-lingual features can be captured; c) With a large amount of training corpus in different languages, XLM can provide powerful cross-lingual representation for downstream tasks, which is very suitable for parallel corpus filtering situations.

We follow the instructions [4] to prepare the training data and train the XLM model. In detail, we use Moses tokenizer to tokenize the text [5], and fastbpe [6] to learn and apply Byte-Pair Encoding. We use 50K BPE codes on the concatenation of all the training data. After applying BPE codes to the training data, we obtain a large vocabulary con-

[3] More details can be found in (Nevado et al., 2003)

[4] https://github.com/facebookresearch/XLM

[5] We do not use the character-/dictionary- based method introduced in Section 2.2.1 to tokenize Khmer here. Performance may be improved with that method, but we have run out of time, unfortunately.

[6] https://github.com/glample/fastBPE

taining around 100K tokens. Therefore, we only keep the top frequent $100,000$ tokens to form the vocabulary and train the XLM.

We use monolingual data in MLM objective and parallel data in TLM objective. In detail, the monolingual data we use are as follows:

- Khmer: all the 14M provided sentences.
- Pashto: all the 6.6M provided sentences.
- English: because the number of english monolingual sentences are so large, we subsample 25M sentences to keep a balance.

All the available parallel sentence pairs (29K en-km and 12K en-ps) are used in TLM objective. For each objective, we hold out 5K sentences or sentence pairs for validation and 5K for the test.

We pre-train the XLM using two different settings on 8 Tesla-V100 GPU: a) **Standard**: The embedding size is 1024, with 12 layers and 64 batch size. b) **Small**: The embedding size is 512, with 6 layers and 32 batch size. The other values of hyperparameters are all set to the default values. The two pre-trained XLM model is then fine-tuned in downstream task and further ensembled.

To score sentence pairs according to their parallelism, classification models are usually used (Xu and Koehn, 2017; Bernier-Colborne and Lo, 2019). In the training phrase, it is formulated as a binary classification problem, whether the sentence pair is semantically similar to each other or not. In the inference phrase, the probability of the positive class is considered as the score of the sentence pair. Therefore, we use the provided parallel sentence pairs as the positive instances, and construct negative instances taking advantage of such positive instances similar to Bernier-Colborne and Lo (2019). Specifically, we generate negative examples in the following ways:

- Shuffle the sentences in source language and target language respectively, and randomly align them.
- Randomly truncate the length of the source sentences or/and target sentences to 3.
- Randomly shuffle the order of the source sentences or/and target sentences.
- Simply swap the source and target sentences. Or replace the source/target sentences with target/source sentences, such that the two sentences are exactly the same.

We only add a linear or convolutional layer on top of the pre-trained XLM model and predict through a sigmoid function. The input of the model is the concatenation of a sentence pair, separated by one [SEP] token. Besides, to tackle the problem that some sentences may be too long, we simply truncate each sentence such that the maximum length of sentence is 128. The dropout rate is set to 0.5.

2.3.2 Reranking

We apply some reranking mechanisms in order to compensate for the latent bias in the XLM-based scorer, and aim to boost the quality of the whole corpus rather than each sentence pair independently.

The first reranking mechanism is based on **language identification**. For some sentences, they may include many tokens that do not belong to the corresponding language, and therefore damage the performance of the machine translation system. This phenomenon is rather common in Khmer-English corpus in particular. We utilize *pycld2* tools [7] to identify the language of the sentences. The scores of those which cannot be identified as the corresponding language are reranked by a discount of α. α is a hyperparameter.

The second reranking mechanism is based on **n-gram coverage**. Because the sentence pairs are scored independently, redundancy may exist in those high-score sentences. To enhance the diversity of the selected corpus, we first sort the sentence pairs in the descending order based on their scores. Next we maintain a n-gram pool for source sentences, and scan the source sentences from the top down. Those sentences that have no n-gram different from those in the pool will receive a discount of β, and both n and β are hyperparameters.

Note that before reranking, we always normalize the score according to their rankings, so that scores provided by different models can be unified. The score of the i-th sentence pair is:

$$score_i = 1 - \frac{rank_i}{N} \tag{5}$$

where i-th pair ranks $rank_i$ in all the sentence pairs and N denotes total number of pairs.

We also try to rerank through language models, but it does not bring improvements. Thus we do not use this reranking mechanism in our submissions.

[7] https://github.com/aboSamoor/pycld2

2.3.3 Ensemble

Different models may capture different features during training and inference. To make use of group wisdom and improve the final performance, we ensemble the following four models by averaging scores:

- Model 1: Standard XLM + Linear Layer. The learning rate of XLM and linear layer are $1e^{-8}$ and $1e^{-5}$ respectively.
- Model 2: Standard XLM + Linear Layer. The learning rate of XLM and linear layer are $1e^{-7}$ and $1e^{-4}$ respectively.
- Model 3: Standard XLM + Convolutional Layer. The learning rate of XLM and linear layer are $5e^{-7}$ and $5e^{-4}$ respectively.
- Model 4: Small XLM + Linear Layer. The learning rate of XLM and linear layer are $5e^{-7}$ and $5e^{-4}$ respectively.

All the models use 16 batch size per GPU.

3 Experiments

We conduct various experiments to evaluate the performance of different models, and select the most proper hyperparameters for both Khmer-English and Pashto-English. Note that **FS** and **FT** denote **From Sratch** and **Fine-Tune** respectively.

Firstly, we conduct the experiments with both the provided aligned sentence pairs (denoted as **Baseline**) and our mined data at the first iteration of the mining module. It shows that our system can outperform the baseline remarkably and the ensemble of four different models can further improve the performance. As Table 2 illustrates, Model 1-4 outperform baseline by about $1 \sim 2$ BLEU in both km-en and ps-en . Besides, the ensemble model performs the best in general.

Table 2: BLEU Scores of Difference Models

Model	km-en		ps-en	
	FS	FT	FS	FT
Baseline	7.28	10.24	9.81	11.37
Model 1	8.33	11.43	11.21	13.11
Model 2	8.96	11.38	**11.43**	13.18
Model 3	8.72	11.29	11.26	12.74
Model 4	9.01	11.27	11.36	13.09
Ensemble	**9.22**	**11.51**	11.28	**13.52**

Next, to verify the effectiveness of the iterative mining strategy in the mining module, we compare the performance of the same ensemble model with different mined data. In our paper, we iteratively mine data for three times, and combine them with the provided sentence-aligned corpus. Table 3 reveals the mining scale each time. As table 4 shows, iteration 3 works best for km-en and iteration 2 for ps-en respectively.

Table 3: The Number of Mined Sentence Pairs

Data	km-en	ps-en
Data 1	238K	200K
Data 2	330K	120K
Data 3	660K	20K

Table 4: BLEU Scores with Different Mined Data

Data	km-en		ps-en	
	FS	FT	FS	FT
+ Data 1	9.22	11.51	11.28	13.52
+ Data 1+2	9.47	11.56	**12.17**	**13.19**
+ Data 1+2+3	**9.84**	**11.62**	12.14	12.69

Finally, by introducing the reranking mechanism, we can further improve the performance, which is shown by Table 5 and 6. Note that $\alpha = 0$ or $\beta = 0$ means it does not have any discount. We select $\alpha = 0.2, n = 2, \beta = 0.2$ and $\alpha = 0, n = 1, \beta = 0.1$ for km-en and ps-en for our submissions.

Table 5: BLEU Scores with Reranking for km-en

	FS	FT
$\alpha = 0, \beta = 0$	9.84	11.62
$\alpha = 0.2, n = 2, \beta = 0.05$	10.40	12.25
$\alpha = 0.2, n = 2, \beta = 0.1$	10.38	11.87
$\alpha = 0.2, n = 2, \beta = 0.2$	**10.50**	**12.45**
$\alpha = 0.2, n = 3, \beta = 0.1$	10.09	12.09
$\alpha = 0.3, n = 2, \beta = 0.05$	10.40	12.25

4 Conclusion

In this paper, we present our submissions to the WMT20 shared task on parallel Corpus filtering and alignment for low-resource conditions. Our Volctrans system consists of two modules: a) Mining module is responsible for mining potential parallel sentence pairs out of the provided document pairs. Word alignment model is utilized and an iterative mining strategy is further taken to boost

Table 6: BLEU Scores with Reranking for ps-en

	FS	FT
$\alpha = 0, \beta = 0$	12.17	13.19
$\alpha = 0, n = 1, \beta = 0.1$	**12.28**	13.34
$\alpha = 0.2, n = 1, \beta = 0.1$	12.15	13.06
$\alpha = 0, n = 2, \beta = 0.1$	12.20	**13.38**
$\alpha = 0, n = 2, \beta = 0.2$	12.20	13.31

the mining performance. b) Scoring module aims to evaluate sentence pairs quality according to their parallelism and fluency properties, by exploiting an XLM-based scorer. We further tune the output score with different reranking mechanism, by considering language detection confidence and n-gram vocabulary coverage. Finally, four models are ensembled to improve the final performance. We also make some analysis through a variety of experiments.

Abstract

This paper describes the system submitted by Papago team for the quality estimation task at WMT 2020. It proposes two key strategies for quality estimation: (1) task-specific pretraining scheme, and (2) task-specific data augmentation. The former focuses on devising learning signals for pretraining that are closely related to the downstream task. We also present data augmentation techniques that simulate the varying levels of errors that the downstream dataset may contain. Thus, our PATQUEST models are exposed to erroneous translations in both stages of task-specific pretraining and finetuning, effectively enhancing their generalization capability. Our submitted models achieve significant improvement over the baselines for Task 1 (Sentence-Level Direct Assessment; EN-DE only), and Task 3 (Document-Level Score).

1 Introduction

With the widespread use of machine translation systems, there is a growing need to evaluate translated results at low-cost. The task of quality estimation (QE) addresses this issue, where the quality of a translation is predicted automatically given the source sentence and its translation. The estimated quality can inform users about the reliability of the translation, or whether it needs to be post-edited.

Previous QE systems generally include pretraining and finetuning steps, where the former step involves masked language modeling (MLM) utilizing large parallel corpora, with the expectation that the models will learn cross-lingual relationships (Kepler et al., 2019; Kim et al., 2019). The models are, in turn, finetuned with task-specific data. However, while the pretraining step involves training data with near-perfect translations, low-quality translations are only introduced during the finetuning step.

	Task1 (Section 2)	Task3 (Section 3)
Perturbations	- Omitted word - Word order - Lexical selection - Repeated phrase	- Omitted word (preposition, determiner) - Word order - Lexical selection - Wrong preposition
Label	- SentenceBERT - BERTScore - GPT-2	- Pseudo-MQM

Figure 1: Overview of our approach for Task 1 and 3.

In this work, we suggest two key strategies that could alleviate this pretrain-finetune discrepancy in QE tasks by: (1) adopting a task-specific pretraining objective which is close to that of the downstream task, and (2) generating abundant task-specific erroneous sentence pairs and their learning signals. Our approach, which is depicted in Figure 1, is motivated from BLEURT (Sellam et al., 2020), where we extend their general approach to the bilingual QE setting. Our submitted systems achieve significant improvements in performance over the baseline systems on WMT20 Shared Tasks for QE (Specia et al., 2020): an absolute gain of $+35.2\%$ in Pearson score for (Task 1) Sentence-Level Direct Assessment (EN-DE), and $+18.4\%$ in Pearson score for (Task 3) Document-Level Score.

2 Sentence-Level QE: Direct Assessment

The task of sentence-level QE for direct assessment (DA) involves predicting the perceived quality of the translation given the source and the translated sentences.

Online, November 19–20, 2020.

on QE, our sentence-level system also utilizes the pretrained multilingual language models such as BERT (Devlin et al., 2018) and Cross-lingual Language Model (XLM) (Conneau and Lample, 2019). As the size of the training corpus for the QE task is very limited (7K sentence pairs), it is crucial to align these models closely to the task using more data in the form of task-specific pretraining.

As opposed to pretraining the models on parallel corpora using the standard MLM approach, we pretrain the models in a multi-task setting using learning signals and data that are arguably more task-specific similar to Sellam et al. (2020).

2.1 Task-Specific Data Augmentation

In order to better align the pretrained models to the QE task, synthetic sentence pairs that contain various types of translation errors are generated from clean parallel corpora[1]. For each target sentence, we generate two perturbed sentences by separately applying one of the four methods described below.

Omitted Word We randomly omit at most three words from the target-side, simulating inadequate translations.

Word Order Based on the part-of-speech (POS) tag for each word in the target sentence, and predefined sequences of POS patterns, we randomly swap two target words if those words match one of the patterns. The POS patterns can be contiguous, e.g., *adjective-space-noun*, or long-ranged, e.g., *noun-*-adjective*. When none of the patterns are matched, we randomly swap two words.

Lexical Selection For each target sentence, we mask out at most three words randomly, and apply mask-filling via a German BERT model from Hugging Face[2]. The purpose of this alteration is to generate fluent but somewhat inadequate target sentences.

Repeated Phrase In order to simulate the repetition problem in translations generated by neural machine translation models, we alter the target sentence by adding a repetition of a random phrase within the sentence. The length of the random phrase is at most three tokens.

[1] `Europarl v10` and `News Commentary v15`

[2] `bert-base-german-cased`, https://huggingface.co/transformers/pretrained_models.html

2.2 Task-Specific Learning Signals

As the goal of the downstream task is to predict the DA scores which represent the "perceived quality" of the translation, we need to consider pretraining signals that can capture the somewhat subjective notion of "good" and "bad" translations.

Consulting the related works, we prepared the three learning signals:

- SentenceBERT score (Reimers and Gurevych, 2019)
- BERTScore (Zhang et al., 2019), extended to multilingual setting
- Target (German) Language Model (GPT-2, Radford et al. (2019)) score

For each sentence pair in the original bilingual corpora as well as the augmented ones, the three types of learning signals are computed, and later used in the task-specific pretraining.

2.2.1 SentenceBERT Score

For a given sentence, SentenceBERT produces a semantically meaningful sentence embedding that can be compared using a distance metric.

We note that when comparing the distance between two sentence vectors, the Kendall rank correlation coefficient (Kendall, 1938) is computed instead of the cosine similarity measure as the former correlates better with the human judgement, possibly because it produces a more widespread range of scores than the latter especially when the dimension of the sentence vectors is high.

In our experiments, we used the publicly available multilingual SentenceBERT model released from UKPLab[3] that supports 13 languages including English and German.

2.2.2 Multilingual BERTScore

While SentenceBERT score looks at the sentence embedding as a whole, BERTScore computes a similarity score for each token in the pair of sentences. We include BERTScore as one of the learning signals because we feared that the mean-pooling of the BERT-embedded tokens within the SentenceBERT model, while effective in extracting the overall meaning of the sentence, may overlook some of the small semantic details within the sentence.

[3] `distiluse-base-multilingual-cased`, https://github.com/UKPLab/sentence-transformers

However, as the original BERTScore is designed to work in monolingual setting, i.e. evaluating a translation against a reference sentence, it needs to be extended in multilingual setting using a multilingual BERT (mBERT) model. Analogous to the original approach, the multilingual BERTScores can be computed in various ways depending on which side we are computing the maximum similarities from.

In our experiments, we devise a metric where we merge both the source- and target-side maximum similarities between tokens with the corresponding inverse document frequency (IDF) weighting; thus, given a sequence of vectorized source and target tokens, s and t, we defined the `mBERTScore` of s and t to be:

$$\frac{S_{s\to t} + S_{t\to s}}{\sum_{s_i \in s} \text{idf}(s_i) + \sum_{t_j \in t} \text{idf}(t_j)}$$

where

$$S_{s\to t} = \sum_{s_i \in s} \text{idf}(s_i) \max_{t_j \in t} \boldsymbol{s_i}^\top \boldsymbol{t_j}$$

$$S_{t\to s} = \sum_{t_j \in t} \text{idf}(t_j) \max_{s_i \in s} \boldsymbol{t_j}^\top \boldsymbol{s_i}$$

2.2.3 Target Language Model Score

While SentenceBERT and multilingual BERTScore can be used as proxies for evaluating the "adequacy" of the translation, empirically, we noticed that they cannot seem to sufficiently represent the "fluency" of translated target sentence. In other words, both metrics may assign high scores to the translated sentence if key source tokens are translated and present in the translation, even when the overall sentence may not be articulate.

To address this issue, the target language model (GPT-2) score is added to the set of learning signals. We simply use the arithmetic mean of the token-level predictions to produce the score for a target sentence. We utilize the pretrained GPT-2 model for German released by Zamia Brain[4].

2.3 Model Architecture

We have two stages for task-specific training, i.e. first with the augmented data and the learning signals, and second with the provided QE dataset (ref. Section 2.4). As the output to predict for each stage is different, we utilize the following two types of model architectures.

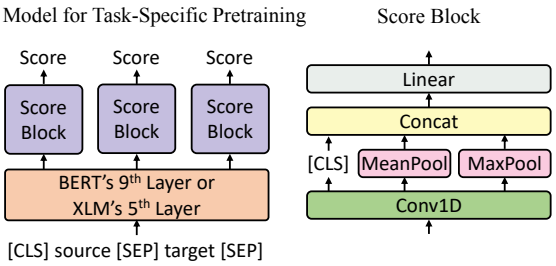

Figure 2: The model architecture (*left*) for the task-specific pretraining using the augmented dataset and learning signals. It consists of three separate Score Blocks (*right*) added on top of the BERT's or XLM's layer.

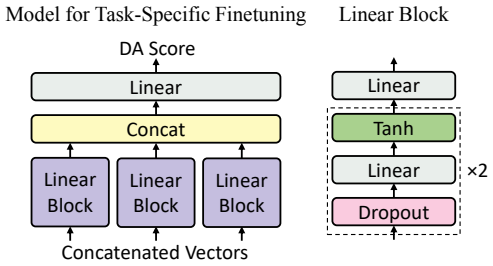

Figure 3: The model architecture (*left*) for the task-specific finetuning using the provided QE dataset. For each concatenated vector computed within each Score Block (c.f. Fig. 2.), a Linear Block (*right*) is added on top of it. The results from the Linear Blocks are concatenated and used to produce the final DA score.

2.3.1 Model for Task-Specific Pretraining

On top of the specific layer of the pretrained mBERT or XLM models, we attach a series of layers called "Score Block" for each type of learning signal as depicted in Figure 2. We utilize the 9th and 5th layer of the BERT and XLM models, respectively, as these layers are reported to be more semantically relevant (Jawahar et al., 2019; Zhang et al., 2019).

In addition to using the vector representation of the `[CLS]` token, utilizing the mean-pooled and max-pooled vectors from all tokens further improved the performance.

2.3.2 Model for Task-Specific Finetuning

Once the task-specific pretraining is completed, we begin the finetuning by adding layers above the concatenation layer within each Score Block, as

[4] `gpt2-german-345M-r20191119`, http://zamia-speech.org/brain

shown in Figure 3. Thus, we have three concatenated vectors being fed to three "Linear Blocks" separately, whose purpose is to reduce the dimensions of the hidden representation, preparing it for the final regression layer.

We note that applying dropout (Srivastava et al., 2014) to these linear layers helps with the performance.

2.4 Task-Specific Training

We experiment with three different types of pretrained models: mBERT[5], XLM trained with MLM (XLM-MLM)[6], and XLM trained with causal language modeling (XLM-CLM)[7]. All of the pretrained models are available at Hugging Face.

2.4.1 Task-Specific Pretraining (TSP)

As the size of the provided QE dataset is small, we make use of the existing parallel data as well as the error-induced synthetic data. For the EN-DE bilingual dataset, we select a subset from this year's training corpora for WMT News Translation Task, summing to just under 10M sentence pairs; for the synthetic dataset, the size is 3.4M.

Given the concatenated source and target sentences as an input, the model for TSP is trained to predict the three types of learning signals in a multi-task setting by minimizing the sum of the mean squared error losses for each signal (ref. Figure 2).

2.4.2 Task-Specific Finetuning (TSF)

Once the model is trained with the augmented data, its parameters are loaded to the model for TSF (ref. Figure 3), and finetuned using the QE dataset. This time, the model learns to predict the mean z-normalized DA score.

3 Document-Level QE: MQM Scoring

Given a source and its translated document, this task involves identifying translation errors and estimating the translation quality of the document based on the taxonomy of the Multidimensional Quality Metrics (MQM)[8]. With the pre-defined MQM taxonomy, human annotators assess whether the translation satisfies the specifications, and from these annotations, an MQM score is obtained. In this work, we focus on building a system that predicts the MQM score for a given pair of source and translated document.

The major difficulty that we encountered in this task was the lack of training data. As the amount of provided data is limited (8,591 sentence pairs), a model that is solely finetuned on this small-scale data was not capable enough to differentiate sentences with varying level of errors.

To address this issue, we propose simple yet effective methods for task-specific data augmentation, and task-specific training framework[9].

3.1 Task-Specific Data Augmentation

We generate erroneous sentence pairs and their pseudo-MQM scores from Europarl and QE training corpus in accordance with the MQM taxonomy.

3.1.1 Generating Erroneous Sentence Pairs

Out of the 45 error categories specified in QE annotations, we select five frequent categories for which we can automatically perturb the target-side of the parallel corpus at little cost. More details on our data augmentation technique for each category are provided below.

Omitted Preposition We introduce an error into the target-side of a sentence pair by randomly omitting one of the French prepositions that exist in the sentence.

Omitted Determiner The same process is done for French determiners as for prepositions.

Wrong Preposition We replace a French preposition with another one. When more than one candidate exists, we choose one at random.

Word Order We exploit grammatical pattern that most descriptive adjectives go after the noun in French sentences (unlike English ones). Using an in-house French POS tagger, we identify post-nominal adjectives and place them in front of the corresponding nouns so that they are now pre-nominal.

Lexical Selection We mask-out target tokens at random positions, and substitute them with tokens predicted by the Camembert language model (Martin et al., 2020).

(1) Omit Preposition	Brûleur deux *plaque* de cuisson anti-adhésive ~~de~~ Coghlan	9	10	-11.1

Table 2: Examples of erroneous sentence pairs generated from the WMT20 QE corpus.

3.1.2 Task-Specific Learning Signal

Once we introduce different types of errors into the target-side sentences, the next step is to obtain pseudo-MQM scores for the altered sentence pairs. Two key elements for computing MQM score are the length of a text, and its total error severity as follows:

$$\text{Pseudo-MQM} = 100(1 - \frac{5.0 * n_{error} + S}{N})$$

where N indicates the length of given target sentence and n_{error} denotes the number of errors introduced in it. We assign 5.0, the most frequent severity, to each perturbation that we make. If an error severity score, S, is assigned to the sentence by human annotators, we add this score to compute the total error severity score.

3.2 Model Architecture

We use pretrained mBERT or XLM[10] as initial parameters. The concatenation of a source sentence and its corresponding target sentence with special symbol tokens is taken as input: `[CLS] source [SEP] target [SEP]`.

We experiment with two strategies for obtaining sentence embeddings. First, we feed a hidden state vector corresponding to `[CLS]` token ($h_{[CLS]}$) to a linear layer to compute a sentence-level MQM prediction of $\hat{y}$:

$$\hat{y} = W h_{[CLS]} + b$$

where W and b are the weight matrix and bias vector of the linear layer, respectively. For the other method, we use the concatenation of a mean-pooled source representation ($s \in \mathbb{R}^n$), mean-pooled target representation ($t \in \mathbb{R}^n$) and their element-wise differences ($|s - t| \in \mathbb{R}^n$) in an attempt to enlarge the model capacity:

$$\hat{y} = W \cdot \text{ReLU}(W_r(s, t, |s - t|) + b_r) + b$$

where $W_r \in \mathbb{R}^{3n \times n}$ and b_r are the weight matrix and bias vector of an intermediate dimension-reducing layer, respectively, and n denotes the dimension of hidden vectors. W and b are the weight matrix and bias vector of the final linear layer.

3.3 Task-Specific Training

We suggest that the pretraining objective should be similar to that of the downstream task in order to mitigate the pretrain-finetune discrepancy (Yang et al., 2019), and fully leverage the erroneous sentence pairs that we generated. For this task, both phases minimize the mean-squared loss function: $l = \frac{1}{K} \sum_{k=1}^{K} \|y_k - \hat{y}\|^2$.

3.3.1 Task-Specific Pretraining (TSP)

We utilize Europarl parallel corpus (English-French) to pretrain our submitted models[11]. To acquire high quality data, we carried out the following filtering processes: (1) language detection (filtering out non-English sentences in the source-side, and non-French sentences in the target-side), (2) length ratio filtering (eliminating sentence pairs with length ratio greater than 1.8).

[10] `xlm-mlm-enfr-1024`

[11] We perform TSP after bringing pretrained parameters of language models as initial weights.

We assume that the remaining sentence pairs do not contain any translation error. Therefore, we assign the total error severity score of zero to these pairs before the augmentation.

About 15.2 million examples[12] are generated with the above-mentioned data augmentation techniques. The detailed examples are provided in Table 1.

3.3.2 Task-Specific Finetuning (TSF)

The next step is to finetune our model using the augmented QE train data. Unlike Europarl corpus, we can fully leverage the MQM scores originally assigned to the QE training dataset. We found that performing the data augmentation with three categories (*Omitted Determiner*, *Omitted Preposition*, and *Wrong Preposition*) effectively improves the performance. The original QE training sentence pairs represent about 5% of 169,997 sentence pairs obtained from the data augmentation. We also provide the augmented examples for QE training data in Table 2.

Since the learning objective is identical to that of the pretraining phase, we can simply train the same model with the augmented downstream task data.

3.4 Document-Level MQM Score

We specify that the models are trained at sentence-level, learning to predict the non-truncated version of MQM scores which could take a range between negative infinity and 100; this is to avoid potential information loss that could arise from the truncation.

Given a document, the document-level MQM score is computed from its sentence-level MQM predictions in a closed form. Afterwards, we truncate negative values to zero.

4 Experimental Results

4.1 Sentence-Level Task

Table 3 shows the Pearson correlation coefficient between the predicted z-normalized DA scores and the reference scores on the development set. We note that the number of parameters for PATQUEST-mBERT (724M) is greater than that of PATQUEST-XLM (616M) models, resulting in the difference in the correlation scores. Nevertheless, computing the arithmetic mean of the scores produced by these three models improves the performance (PATQUEST-ensemble).

Model	Pearson's r ↑
PATQUEST-mBERT	0.486
PATQUEST-XLM-MLM	0.450
PATQUEST-XLM-CLM	0.452
PATQUEST-ensemble	**0.501**

Table 3: Results on the *development* set for Task 1 EN-DE.

Model	Pearson's r ↑	MAE ↓	RMSE ↓
Baseline	0.146	0.679	0.967
PATQUEST-mBERT w/o synth. data	0.429	0.462	0.632
PATQUEST-ensemble w/o synth. data	0.457	0.464	0.640
PATQUEST-ensemble	**0.498**	**0.454**	**0.637**

Table 4: Submission results on the *test* set for Task 1 EN-DE.

The final result on the QE test set is shown in Table 4. We observe that finetuning the model with the additional error-induced synthetic data improves the performance as well as ensembling the models.

Our final submitted system (PATQUEST-ensemble) finished 4th out of the 15 submitted systems[13] in the final ranking of the sentence-level QE task for English-German. In order to train a generally applicable QE system, we did not make use of the data such as internal information from the NMT models and in-domain Wikipedia texts that could be extracted from the provided Wikipedia titles.

4.2 Document-Level Task

The validation results on development set are shown in Table 5. Both PATQUEST-mBERT and PATQUEST-XLM models use representations from [CLS] token. We build another two models, PATQUEST-mBERT variant 1 and 2, using the concatenations of mean-pooled source representations, mean-pooled target representations, and their element-wise differences.

Table 6 shows the test results of our submitted PATQUEST models. For PATQUEST-ensemble, we compute an average from the four models enumerated in Table 5.

In Table 7, the effectiveness of our training scheme and data augmentation techniques is illustrated via an ablation study. Note that "Pretrained mBERT (A)" in the table refers to the mBERT

[12]The size of the original Europarl English-French parallel corpus is about 2M sentence pairs.

[13]Excluding the disqualified team.

Model	Pearson's r ↑	MAE ↓	RMSE ↓
PATQUEST-mBERT	0.431	14.401	22.330
PATQUEST-mBERT variant 1	0.406	14.418	22.872
PATQUEST-mBERT variant 2	0.380	14.909	23.215
PATQUEST-XLM	0.374	16.245	23.647

Table 5: Results on the *development* set of WMT20 document-level task.

Model	Pearson's r ↑	MAE ↓	RMSE ↓
Baseline	0.389	19.939	26.608
PATQUEST-mBERT	0.529	16.214	24.437
PATQUEST-XLM	0.546	15.821	23.846
PATQUEST-ensemble	**0.573**	**15.611**	**23.327**

Table 6: Submission results of PATQUEST models on the *test* set of WMT20 document-level task.

model that is finetuned on the original QE data without any task-specific training. Both TSP and TSF enhance the generalization ability of model. Note that the mBERT model trained via TSP and TSF, "A + TSP + TSF", is the same model as PATQUEST-mBERT which itself achieves a significant improvement over the baselines as shown in Table 6.

Our final system (PATQUEST-ensemble) submitted for the document-level QE task, came 1st out of the three submitted systems[14]. Similar to our sentence-level system, our document-level system also did not utilize any internal information from the NMT models and in-domain Wikipedia data tailored to the benchmark.

5 Conclusion

In this paper, we present a task-specific pretraining scheme for the QE task. Our pretraining objective is devised so that it is closely related (Task 1) or identical (Task 3) to the finetuning objective. In addition, the models are exposed to abundant amount of error-induced translations generated from large parallel corpora, effectively alleviating the issue of data scarcity.

Our proposed models yield significant improvement over the baseline systems for the two tasks.

[14]Excluding the disqualified team

Model	Pearson's r ↑	MAE ↓	RMSE ↓
Pretrained mBERT (A)	0.263	16.146	23.090
A + TSF	0.341 (+ 0.078)	15.302	23.749
A + TSP	0.375 (+ 0.112)	15.496	23.444
A + TSP + TSF	0.431 (+ 0.168)	14.401	22.330

RTM Ensemble Learning Results at Quality Estimation Task

Ergun Biçici
ergun.bicici@boun.edu.tr
Electrical and Electronics Engineering Department, Boğaziçi University
orcid.org/0000-0002-2293-2031

Abstract

We obtain new results using referential translation machines (RTMs) with predictions mixed and stacked to obtain a better mixture of experts prediction. We are able to achieve better results than the baseline model in Task 1 subtasks. Our stacking results significantly improve the results on the training sets but decrease the test set results. RTMs can achieve to become the 5th among 13 models in ru-en subtask and 5th in the multilingual track of sentence-level Task 1 based on MAE.

1 Introduction

Quality estimation task in WMT20 (Specia et al., 2020) (QET20) address machine translation (MT) performance prediction (MTPP), where translation quality is predicted without using reference translations, at the sentence- (Tasks 1 and 2), word- (Task 2), and document-levels (Task 3). Task 1 predicts the sentence-level direct assessment (DA) in 7 language pairs categorized according to the MT resources available:

- high-resource, English–German (en-de), English–Chinese (en-zh), and Russian-English (en-ru)
- medium-resource, Romanian–English (ro-en) and Estonian–English (et-en), and
- low-resource, Sinhalese–English (si-en) and Nepalese–English (ne-en).

en-ru contains sentences from both Wikipedia and Reddit articles while others use only Wikipedia sentences with 7000 sentences for training, 1000 for development, and 1000 for testing. The target to predict in Task 1 is z-standardised DA scores, which changes the range from $[0, 100]$ for DA scores to $[3.178, -7.542]$ in z-standardized DA scores.

			RTM interpretants		
Task	Train	Test	setting	Training	LM
Task 1 (en-de)	8000	1000	bilingual	0.3 M	5 M
Task 1 (en-zh)	8000	1000	monolingual en	0.2 M	3.5 M
Task 1 (si-en)	8000	1000	monolingual en	0.2 M	3.5 M
Task 1 (ne-en)	8000	1000	monolingual en	0.2 M	3.5 M
Task 1 (et-en)	8000	1000	monolingual en	0.2 M	3.5 M
Task 1 (ro-en)	8000	1000	monolingual en	0.2 M	3.5 M
Task 1 (ru-en)	8000	1000	bilingual	0.2 M	4 M
Task 2 (en-de)	8000	1000	bilingual	0.3 M	5 M
Task 2 (en-zh)	8000	1000	monolingual en	0.2 M	3.5 M

Table 1: Number of instances in the tasks and the size of the interpretants used.

The target to predict in Task 2 is sentence HTER (human-targeted translation edit rate) scores (Snover et al., 2006) and binary classification of word-level translation errors. We participated in sentence-level subtasks, which include English-German and English-Chinese in Task 2. Table 1 lists the number of sentences in the training and test sets for each task and the number of instances used as interpretants in the referential translation machine (RTM) (Biçici, 2018; Biçici and Way, 2015) models (M for million).

We tokenize and truecase all of the corpora using Moses' (Koehn et al., 2007) processing tools.[1] LMs are built using `kenlm` (Heafield et al., 2013).

2 RTM for MTPP

We use RTM models for building our prediction models. RTMs predict data translation between the instances in the training set and the test set using interpretants, data selected close to the task instances in bilingual training settings or monolingual language model (LM) settings. Interpretants provide context for the prediction task and are used during the derivation of the features measuring the closeness of the test sentences to the

Proceedings of the 5th Conference on Machine Translation (WMT), pages 999–1003
Online, November 19–20, 2020.

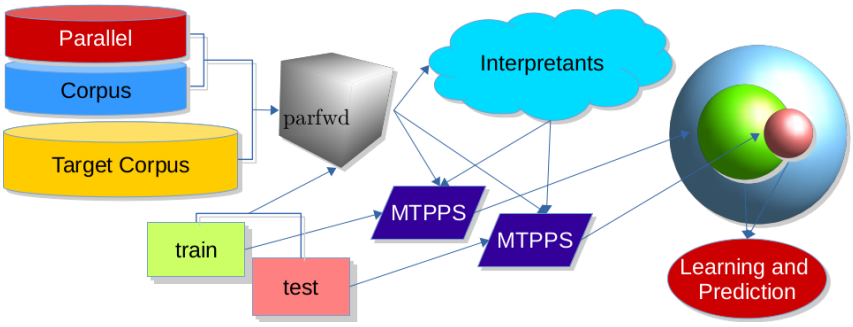

Figure 1: RTM depiction: parfwd selects interpretants close to the training and test data using parallel corpus in bilingual settings and monolingual corpus in the target language or just the monolingual target corpus in monolingual settings; an MTPPS use interpretants and training data to generate training features and another use interpretants and test data to generate test features in the same feature space; learning and prediction takes place using these features as input.

training data, the difficulty of translating them, and to identify translation acts between any two data sets for building prediction models. With the enlarging parallel and monolingual corpora made available by WMT, the capability of the interpretant datasets selected to provide context for the training and test sets improve as can be seen in the data statistics of `parfwd` instance selection, parallel feature weight decay (Biçici, 2019). RTMs use `parfwd` for instance selection and machine translation performance prediction system (MTPPS) (Biçici et al., 2013; Biçici and Way, 2015) for obtaining the features, which includes additional features from word alignment. Figure 1 depicts RTMs and explains the model building process.

Additionally, we included the sum, mean, standard deviation, minimum, and maximum of alignment word log probabilities as features in Task 1. In Task 2, we included word alignment displacement features including the average of source and target displacements relative to the length of the source or target sentences respectively and absolute displacement relative to the maximum of source and target sentence lengths.

Instead of resource based discernment, we treated en-de of Tasks 1 and 2 and ru-en as bilingual tasks where significant parallel corpora are available from WMT from previous years and the rest as monolingual, using solely English side of the corpora for deriving MTPP features. In accord, we treat en-de and ru-en as parallel MTPP and the rest as monolingual MTPP. RTM benefits from relevant data selection to be used as interpretants in both monolingual and bilingual settings. The related monolingual or bilingual datasets are used during feature extraction for the machine learning models of MT.

The machine learning models we use include ridge regression (RR), kernel ridge regression, support vector regression (SVR) (Boser et al., 1992), gradient tree boosting, extremely randomized trees (Geurts et al., 2006), and multi-layer perceptron (Bishop, 2006) as learning models in combination with feature selection (FS) (Guyon et al., 2002) and partial least squares (PLS) (Wold et al., 1984) where most of these models can be found in `scikit-learn`.[2] We experiment with:

- including the statistics of the binary tags obtained as features extracted from word-level tag predictions for sentence-level prediction,
- using RR to estimate the noise level for SVR, which obtains accuracy with 5% error compared with estimates obtained with known noise level (Cherkassky and Ma, 2004) and set $\epsilon = \sigma/2$.

We use Pearson's correlation (r), mean absolute error (MAE), root mean squared error (RMSE), relative absolute error (RAE), relative MAE (MAER), and mean RAE relative (MRAER) as evaluation metrics (Biçici and Way, 2015). Our best non-mix results are in Table 2 achieving 6th rank at best among 15 models in general.

3 Mixture of Experts Models

We use prediction averaging (Biçici, 2018) to obtain a combined prediction from various prediction outputs better than the components, where the performance on the training set is used to obtain

	en-zh	0.3864 (15)	0.1585 (14)	0.1959 (15)

Table 2: RTM test results in sentence-level MTPP in tasks 1 and 2 using the best non-mix result with (ranks). r_P is Pearson's correlation.

weighted average of the top k predictions, $\hat{y}$ with evaluation metrics indexed by $j \in J$ and weights with w:

$$\begin{aligned} w_{j,i} &= \frac{w_{j,i}}{1-w_{j,i}} \\ \hat{\boldsymbol{y}}_{\mu_k} &= \frac{1}{k}\sum_{i=1}^{k}\hat{\boldsymbol{y}}_i && \text{MEAN} \\ \hat{\boldsymbol{y}}_{j,w_k^j} &= \frac{1}{\sum_{i=1}^{k} w_{j,i}}\sum_{i=1}^{k} w_{j,i}\,\hat{\boldsymbol{y}}_i \\ \hat{\boldsymbol{y}}_k &= \frac{1}{|J|}\sum_{j\in J}\hat{\boldsymbol{y}}_{j,w_k^j} && \text{MIX} \end{aligned} \quad (1)$$

We assume independent predictions and use $p_i/(1-p_i)$ for weights where p_i represents the accuracy of the independent classifier i in a weighted majority ensemble (Kuncheva and Rodríguez, 2014). We use the MIX prediction only when we obtain better results on the training set. We select the best model using r and mix the results using r, RAE, MRAER, and MAER. We filter out those results with higher than 0.875 relative evaluation metric scores.

We also use generalized ensemble method (GEM) as an alternative to MIX to combine using weights and correlation of the errors, $C_{i,j}$, where GEM achieves smaller error than the best combined model (Perrone and Cooper, 1992):

$$\begin{aligned} \hat{\mathbf{y}}_{\text{GEM}} &= \sum_{i=1}^{L} w_i\psi_i(\mathbf{x}) = \mathbf{y} + \sum_{i=1}^{L} w_i\epsilon_i \\ C_{i,j} &= E[\epsilon_i, \epsilon_j] = (\psi_i(\mathbf{x}) - \mathbf{y})^T(\psi_i(\mathbf{x}) - \mathbf{y}) \\ w_i &= \frac{\sum_{j=1}^{L} C_{i,j}}{\sum_{k=1}^{L}\sum_{j=1}^{L} C_{k,j}} \end{aligned}$$

Model combination (Figure 2) selects top k combined predictions and adds them to the set of predictions where the next layer can use another model combination step or just pick the best model according to the results on the training set. We use a two layer combination where the second layer is a combination of all of the predictions obtained. The last layer is an arg max.

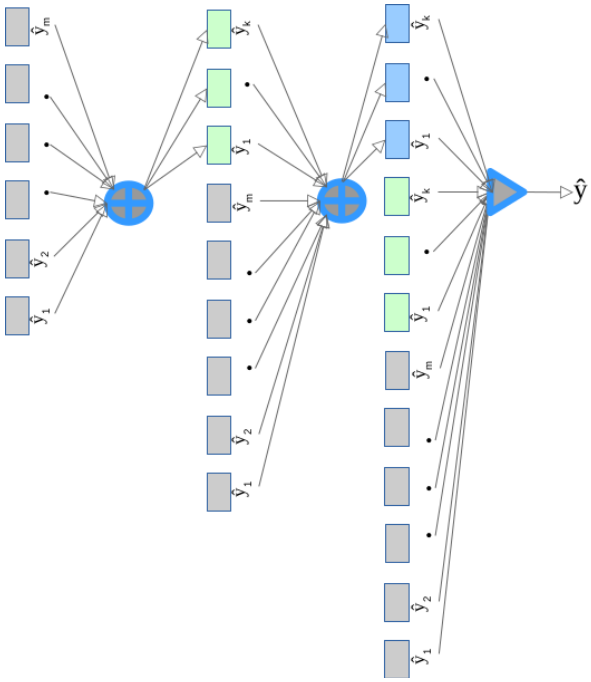

Figure 2: Model combination.

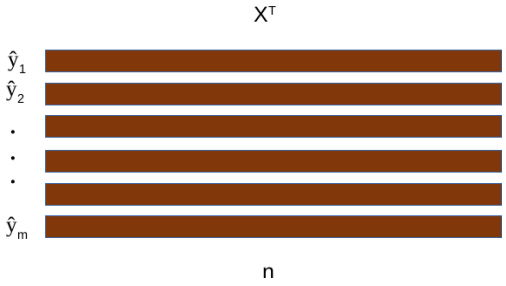

Figure 3: Stacking use predictions as features.

We also use stacking (STACK) to build higher level models using predictions from base prediction models where they can also use the probability associated with the predictions (Ting and Witten, 1999). The stacking models use the predictions from predictors as features and additional selected features and build second level predictors. Stacking with m predictors is depicted in Figure 3 where predictions are used as features for the predictors in the next level. Martins et al. (2017) used a hybrid stacking model to combine the word-level predictions from 15 predictors using neural networks with different initializations together with the previous features from a linear model. Our stacking results also use top features from the data similar to the pass through feature of the stacking regressor of sklearn.[3] For these features, we con-

Table 4: RTM test results in sentence-level MTPP in tasks 1 and 2 using the best GEM mix + mix result.

sider at most the top 15% of the features selected with feature selection.

RTM can achieve better results than the baseline model in Task 1 in all tasks participated [4] where the baseline is a neural predictor-estimator approach implemented in OpenKiwi (Kepler et al.). Our training r_P results are in Table 3. Our test set results using GEM mix and MIX are in Table 4 where we obtain 5th rank among 11 submissions in the multilingual subtask according to MAE. Official evaluation metric is r_P.

Before model combination, we further filter prediction results from different machine learning models based on the results on the training set to decrease the number of models combined and improve the results. A criteria that we use is MREAR ≥ 0.875 since MRAER computes the mean relative RAE score, which we want to be less than 1. In general, the combined model is better than the best model in the set and stacking achieves better results than MIX on the training set. However, stacking models significantly improve the results on the training data but obtain decreased scores on the test set (Table 5).

4 Conclusion

Referential translation machines pioneer a language independent approach and remove the need to access any task or domain specific information or resource and can achieve top performance in automatic, accurate, and language independent prediction of translation scores. We present RTM results with ensemble models and stacking.

Abstract

This paper describes our system of the sentence-level and word-level Quality Estimation Shared Task of WMT20. Our system is based on the QE Brain, and we simply enhance it by injecting noise at the target side. And to obtain the deep bi-directional information, we use a masked language model at the target side instead of two single directional decoders. Meanwhile, we try to use the extra QE data from the WMT17 and WMT19 to improve our system's performance. Finally, we ensemble the features or the results from different models to get our best results. Our system finished fifth in the end at sentence-level on both EN-ZH and EN-DE language pairs.

1 Introduction

Quality Estimation (QE) is a task to predict the quality of translations without relying on any references. QE plays a critical role in machine translation to reduce human efforts, such as deciding whether a translation is good enough for post-editing and indicating what edits are needed. This paper describes our system of the Shared Task on Word and Sentence-Level (QE Tasks 2) at WMT20. With the post-edited translations, all the quality scores can be computed automatically by TER-COM (Snover et al., 2006).

Traditional QE models (Kozlova et al., 2016) use some time-consuming and expensive hand-craft features to represent the translation pairs. With the great success of deep neural networks in natural language processing (NLP), some researches have begun to apply automatic neural features to do QE tasks (Chen et al., 2017; Shah et al., 2016). However, the rare QE data can't fully release the power of deep neural networks. To address this problem, researchers try to transfer bilingual knowledge from parallel data to QE tasks (Fan et al., 2018). These works usually follow a predictor-estimator framework (Kim et al., 2017). This framework first trains the predictor to predict each token of the target sentence given the source and the context of the target sentence on parallel data. Then, the estimator is trained using the features of QE data produced by the predictor.

However, existing predictor-estimator frameworks cannot fully use the information from parallel data because of the discrepancy of data quality between the predictor and the estimator. The predictor is trained on parallel data, which are nearly no errors in translations. While the translations in QE data is generated by a real machine translation system and may have some errors. When the estimator is training on the QE data, the predictor needs to extract the features of translations with some errors, which is quite different from the parallel data. Thus, the predictor can't extract features well.

To fix this problem, we present two different approaches in this paper. The first model masks some tokens at the target side but still need to predict every token correctly, and it enhances the ability of the model to deal with translations with errors. And to obtain the deep bi-directional information, we use a masked language model at the target side instead of two single directional decoders. Meanwhile, we try to use the extra QE data, which are from the WMT17 and WMT19 to improve our system's performance. Finally, we ensemble the features or the results from different models to get our best results. Our system finished fifth in the end at sentence-level on both EN-ZH and EN-DE language pairs of the WMT20 QE shared tasks (Specia et al., 2020).

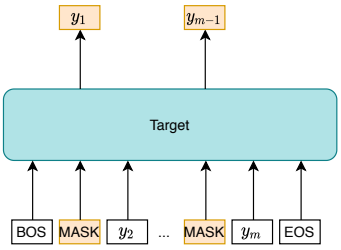
(a) QE Brain mask.



(b) MTLM.

Figure 1: To save space, we do not show the source encoders of these models in the figure. (a) shows the QE Brain mask system, and it simply enhances the original QE Brain system by simply masking tokens at the target side. (b) uses a masked language model at the target side to obtain deep bidirectional information.

2 Methods

As we all know, using different sub-models for ensemble will have better results (Krogh and Vedelsby, 1995). We ensemble different methods in our system, some of them are existing methods, and the others are proposed by us. Next, we will describe these methods.

2.1 Existing Methods

2.1.1 QUETCH

QUETCH (Kreutzer et al., 2015) (QUality Estimation from scraTCH) is a multilayer perceptron model trained without auxiliary parallel data. The embeddings of input passed through one linear layer with tanh activation functions and then one output layer with softmax activation functions, one linear layer with tanh activation functions, one output layer with softmax activation functions. QUETCH only outputs OK/BAD probabilities for each word in the word-level task. Similar to (Martins et al., 2017), we estimate HTER with the fraction of BAD labels for the sentence-level task.

2.1.2 NuQE

NuQE (Martins et al., 2016) (NeUral Quality Estimation) can be seen as a stronger version of QUETCH by using complex neural networks. The architecture of NuQE consists of one embeddings layer, one linear layer, one bi-directional GRU layer, two other linear layers. The input and output of NuQE is the same as QUETCH. We use QUETCH and NuQE as implemented in OpenKiwi (Kepler et al., 2019) [1].

2.1.3 QE Brain

QE Brain (Fan et al., 2018) is based on the predictor-estimator framework. The predictor uses transformer neural networks and will be pretrained on the parallel corpus. The model consists of encoder and bi-directional decoder to encode the source sentence $\mathbf{X} = \{x_1, x_2, \ldots, x_n\}$ and predict each token in the target sentence $\mathbf{Y} = \{y_1, y_2, \ldots, y_m\}$ with the help of hidden representations of the source sentence, respectively.

When training the Bi-LSTM (Graves and Schmidhuber, 2005), which is used as the estimator, the source sentence and translation are fed into the predictor to extract features. Similar to common predictor-estimator methods, QE Brain uses the hidden state of the final layer in the predictor as model derived features. They also extract the difference between the probability of generating the current token and the most likely token as mismatching features. Finally, the estimator concatenate model derived features and mismatching features to predict the word-level tags $\mathbf{O}$ and sentence-level HTER q.

Our proposed models are based on the QE Brain.

2.2 Proposed Methods

2.2.1 Masked QE Brain

Researches used to transfer bilingual knowledge from parallel data to QE tasks, however, the data distribution between parallel data and QE data is different. The translations in QE data are generated by a real machine translation system, and there will be some errors in these translations. While the translations in parallel data generated by humans, and there are nearly no errors. It means, the predictor trained on parallel data can not perform well when it is feeding with translations with errors because the contexts at the target side are different.

[1] https://unbabel.github.io/OpenKiwi.

Pair	Dataset	Train	Dev	Test
EN-DE	WMT20	7,000	1,000	1,000
	WMT19	13,442	-	-
	WMT17	23,000	-	-
EN-ZH	WMT20	7,000	1,000	1,000

Table 1: The statistics of QE dataset used in our system for the WMT20 QE shared task.

Pair	Train	Dev
EN-DE	23,438,059	2,000
EN-ZH	7,460,939	2,000

Table 2: Parallel Dataset statistics used in our system. We divide parallel data into a training set and development set.

To partially alleviate this problem, we proposed the masked QE Brain, as shown in Figure 1(a).

The motivation for our method is simple. We want to enhance the predicting ability of the model in the wrong contexts. To achieve this goal, when training the predictor on parallel data, we mask some tokens in the translation. And the predictor needs to make the same prediction as they are feeding with the complete pair. The other part is the same as the original version of the QE Brain.

2.2.2 Masked Target Language Model

The QE Brain and Masked QE Brain use a bi-directional decoder at the target side to obtain the information from both sides. However, this architecture is just a shallow concatenation which can not truly get the information from both sides (Devlin et al., 2018).

Thanks to the masked tokens in target sentences of Masked QE Brain, we can easily use a masked language model (Devlin et al., 2018) at the target side instead. We call this model the Masked Target Language Model (MTLM), and the format of the input is just the same as Masked QE Brain, as shown in Figure 1(b). They both input the source sentence $\mathbf{X}$, the masked target sentence $\mathbf{Y}'$. And the MTLM only need to predict the right tokens of these masked ones at the target side while Masked QE Brain needs to predict all the tokens.

3 Experiments

3.1 Dataset

3.1.1 Data statistics

QE Dataset The QE tasks of WMT20 contains both EN-DE language pair and EN-ZH language pair. They both have sentence-level and word-level tasks. Meanwhile, the word-level task contains the prediction for source tokens, target tokens, and target taps. In our paper, we only report word-level results on target tokens. In our work, we also use the EN-DE QE dataset of WMT17 and WMT19 to help train an ensemble model. The statistics of QE datasets are shown in Table 1.

Parallel Dataset For the EN-DE language pair, we use the data officially released by the organizers. And for the EN-ZH language pair, we use the parallel data from the WMT18 EN-ZH translation task. The statistics of parallel datasets are shown in Table 2.

3.1.2 Preprocess

EN-DE We use BPE (Sennrich et al., 2015) to segment both the English and German texts, and the BPE step is set to 30,000. We learn the BPE code jointly but build the two vocabularies separately. The size of EN is 14,112; the size of DE is 23,458.

EN-ZH We also use BPE to segment English texts here, and the setting is the same as those in EN-DE. The final size is 34,466. For Chinese texts, we keep all the sentences in the original QE dataset, and then use jieba[2] to segment other Chinese sentences in the parallel dataset. We choose the top 40,000 tokens of the frequency as the vocabulary.

3.2 Settings

Metrics The metric of sentence-level QE is Pearson's Correlation Coefficient. And the metrics of word-level QE are F1-MULT (the products of both positive and negative examples) and Matthews's Correlation Coefficient.

Hyper-parameters

- NuQE. The hidden size is [400, 200, 100, 50].
- QUETCH. The hidden size is [100, 50].
- QE Brain. The predictor contains one encoder and two decoders of 6 layers with 512 hidden units. The estimator is a Bi-LSTM, and its hidden size is 512.

	f-ensemble	66.02	-	-
	r-ensemble	62.13	-	-
	v-ensemble	-	51.81	45.33

Table 3: Results of WMT20. f-ensemble means we ensemble different methods by features, r-ensemble means we ensemble different methods by their results and v-ensemble means different methods vote for an ensemble result.

- QE Brain mask. It is all the same as the QE Brain.
- MTLM. The predictor contains one encoder and one decoder of 6 layers with 512 hidden units. And the estimator is the same as the QE Brain.

3.3 Singe Model Results

Table 3 shows the single model results of our system. Different models are using the same parallel data and only using the QE dataset of WMT20.

The NuQE and QUETCH are only trained on the QE dataset, while the other methods are also trained on extra parallel datasets. We can see that the performance of NuQE and QUETCH is far from that of these models that have extra bilingual knowledge.

Compare with the original QE Brain, our two proposed models can have a big improvement.

3.4 Data Ensemble

We train to enhance our system by using other QE datasets, mainly from WMT17 and WMT19. We only try this on the EN-DE language pair. As we can see in Table 4, if we use more QE data, the performance can get a big improvement easily.

3.5 Model Ensemble

We also try to ensemble different methods and finally get the best result. For sentence-level, we try two different ways. First, we use QE Brain, QE Brain mask, and MTLM as a feature extractor. The features from the three models will be combined and then used to predict the hter scores. Second, we simply collect the predictions of different methods on the training set, development set and test set. The training predictions will be feed into a dense layer and used to predict true hter score, development predictions will be used to early stop. Finally, we will use the trained dense layer to deal with the test predictions.

For word-level, we simply use voting to ensemble different models. The results are shown in Table 3.

3.6 Final Results

Table 5 shows our final results of WMT20 on the web pages. Our system does not contain predictions on target gaps on the word-level, so we just combine the results on gaps from NuQE and QUETCH and our results on target tokens to build the final result.

Method	Dataset	Sent-level Dev	Word-level Dev	
			F1-MULT	MCC
QE Brain	WMT20	48.70	34.68	28.74
	ensemble	53.44	39.04	35.04
QE Brain mask	WMT20	53.34	35.15	30.17
	ensemble	54.87	40.05	35.25
MTLM	WMT20	49.77	39.68	33.99
	ensemble	53.38	43.40	36.41

Table 4: Ensemble results of the WMT20 EN-DE language pair, we train the QE systems on the combination of WMT20, WMT19, and WMT17 dataset.

Pair	Sent-level	Word-level
EN-DE	61.81 (5th)	45.11 (6th)
EN-ZH	64.23 (5th)	55.13 (6th)

Table 5: Final results and rank of WMT20 on the web page, the sentence-level metric is Pearson's Correlation Coefficient, and the word-level metric is the Matthews's Correlation Coefficient.

4 Conclusion

This paper describes our system of the WMT20 QE shared task. Our work mainly follows the QE Brain. To bridge the gap between parallel data and QE data, we use a simple way to bring noise into target sentences of parallel data. And to achieve deep bidirectional information, we use a masked language model at the target side. Experiments show that our two-step approaches achieve improvements. Meanwhile, we try to train our models on more QE data with the same language pair and ensemble different methods through different ways to get our final results.

Abstract

This paper presents our submission to the WMT2020 Shared Task on Quality Estimation (QE)[1]. We participate in `Task 1` and `Task 2` focusing on sentence-level prediction. We explore (a) a black-box approach to QE based on pre-trained representations; and (b) glass-box approaches that leverage various indicators that can be extracted from the neural MT systems. In addition to training a feature-based regression model using glass-box quality indicators, we also test whether they can be used to predict MT quality directly with no supervision. We assess our systems in a multilingual setting and show that both types of approaches generalise well across languages. Our black-box QE models tied for the winning submission in four out of seven language pairs in `Task 1`, thus demonstrating very strong performance. The glass-box approaches also performed competitively, representing a lightweight alternative to the neural-based models.

1 Introduction

Quality Estimation (QE) (Blatz et al., 2004; Specia et al., 2009) is an important part of Machine Translation (MT) pipeline. It allows us to evaluate how good a translation is without comparison to reference sentences. As part of the WMT20 Shared Task on Quality Estimation, two sentence-level tasks were proposed. In `Task 1`, participants are asked to predict human judgements of MT quality generated following a methodology similar to Direct Assessment (DA) (Graham et al., 2017). The goal of `Task 2` is to estimate the post-editing effort required in order to correct the MT outputs and measured using the HTER metric (Snover et al., 2006).

This year's task is different from the previous years in two important aspects: (i) the data includes seven language pairs, which are very different both typologically and in terms of translation quality; and (ii) the participants were provided with neural MT (NMT) models that were used for translation. We take advantage of this set up to compare black-box and glass-box approaches to QE. Furthermore, we test both approaches in a multilingual setting.

The rest of this paper is organised as follows. Section 2 describes the glass-box (2.1) and black-box (2.2) QE methods that we explore in our submissions. Section 3 describes the dataset used for the WMT2020 Shared Task on Quality Estimation. Section 4 provides our experimental settings, whereas Section 5 presents the results. Conclusions are given in Section 6.

2 Approach

Below we first describe our glass-box submissions based on the quality indicators that can be obtained as a by-product of decoding with an NMT system. Second, we present our neural-based QE submissions, which explore transfer learning with pre-trained representations. In both cases, we describe how QE is addressed as a multilingual task.

2.1 Glass-box

Glass-box approaches to QE are based on information from the NMT system used to translate the sentences, rather than looking at source and target sentences as in black-box QE, or using external resources. We rely on our previous work on glass-box QE that explores NMT output distribution to capture predictive uncertainty as a proxy to MT quality. Specifically, we use three groups of unsupervised quality indicators from Fomicheva et al. (2020).

[*] Equal contribution.

Proceedings of the 5th Conference on Machine Translation (WMT), pages 1010–1017

Probability Features These features are based on the output probability distribution from a deterministic NMT system:

- Average word-level log-probability for the translated sentence (**TP**);
- Variance of word-level log-probabilities (**Sent-Var**); and
- Entropy of the softmax output distribution (**Softmax-Ent**).

Dropout Features This group of features also rely on output probability distribution but use uncertainty quantification based on the Monte Carlo dropout method to get more accurate QE results. This method consists of performing several forward passes through the network with parameters perturbed by dropout, collecting posterior probabilities and using the resulting distribution to estimate predictive uncertainty (Gal and Ghahramani, 2016).

- Expectation (**D-TP**) and variance (**D-Var**) over the NMT log-probability generated with Monte Carlo dropout;
- A ratio of **D-TP** and **D-Var** as described in Fomicheva et al. (2020) (**D-Combo**); and
- Lexical similarity between MT hypotheses generated with Monte Carlo dropout (**D-Lex-Sim**).

Attention Features We compute the entropy of encoder-decoder attention weights for each target token and then average token-level entropies to obtain a sentence-level measure. Given that the NMT systems used to generate the translations are based on the Transformer architecture where attention is computed at multiple layers and attention heads, there are [Layers $\times$ Heads] of averaged entropies for each sentence. Fomicheva et al. (2020) summarise them by taking the average or minimum value to obtain an unsupervised attention-based metric. By contrast, here we use the averaged entropies of attention weights coming from each head and layer combination as features in our regression model.

Algorithms We use the above groups of features as input for Random Forest (Ho, 1995) and XGBoost (Chen and Guestrin, 2016) regression algorithms. We also submitted the two best performing indicators from Fomicheva et al. (2020) with no supervision: **D-TP** and **D-Lex-Sim**.

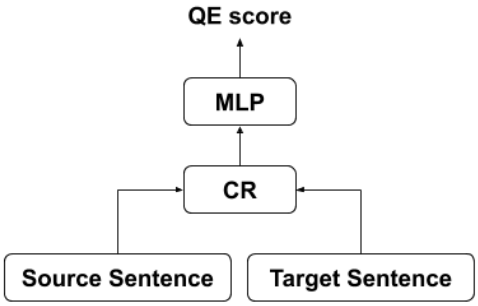

Figure 1: Black-box QE model built on top of contextualised representations (CR).

Multilinguality We hypothesise that system-internal indicators described above are by and large independent on the language pair, given that no linguistic information is directly used. Therefore, to build a multilingual QE system, i.e. a single model that can be used to predict quality for multiple language pairs, we simply concatenate the available data for all languages and use it for training our regression models. Note that we do not add any language identification markers and the system does not require them for making predictions. This can be useful for multilingual translation systems where the user does not need to identify the input languages, and especially for zero-shot settings where a given language pair may not have been seen at training time.

2.2 Black-box

We explore a baseline neural QE model and a multitask learning QE model, both of which are built on top of pre-trained contextualised representations (CR) such as BERT (Devlin et al., 2019) and XLM-R (Conneau et al., 2020).

Baseline QE model (BASE) Given a source sentence s^X in language X and a target sentence s^Y in language Y, we model the QE function f by stacking a 2-layer multilayer perceptron (MLP) on the vector representation of the [CLS] token from a contextualised representations model (CR):

$$\begin{aligned} f(s^X, s^Y) = & W_2 \cdot ReLU(\\ & W_1 \cdot E_{cls}(s^X, s^Y) + b_1 \\ &) + b_2 \end{aligned} \quad (1)$$

where $W_2 \in \mathbb{R}^{1\times 4h}$, $b_2 \in \mathbb{R}$, $W_1 \in \mathbb{R}^{4h\times h}$ and $b_1 \in \mathbb{R}^{4h}$. E_{cls} is a function that extracts the vector representation of the [CLS] token after encoding the concatenation of s^X and s^Y with CR and

ReLU is the Rectified Linear Unit activation function. Note that h is the output dimension of E_{cls}. We explore two training strategies: The **bilingual (BL)** strategy trains a QE model for every language pair while the **multilingual (ML)** strategy trains a single multilingual QE model for all language pairs, where the training data is simply pooled together without any language identifier. We note that this multilingual model here corresponds to a pooled, single-task learning approach.

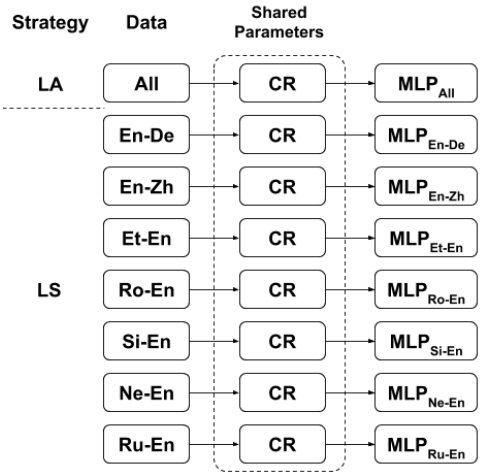

Figure 2: Multi-task learning QE model (MTL) with a shared BERT or XLM-R encoder.

Multi-task Learning QE Model (MTL) We explore multi-task learning to determine whether having parameter sharing across languages is beneficial, and to what degree having language-specific predictors can boost performance. We experiment with a multi-task approach where we concurrently optimise multiple QE BASE models that share parameters across languages. We jointly train two types of models: 1) language-specific (LS), which share parameters through a shared encoder but have different prediction layers; and 2) a language-agnostic (LA) model which also shares parameters for the prediction layer. We refer to these two models as **MTL-LA** and **MTL-LS**.

As seen in Figure 2, the MTL-LS submodels and MTL-LA submodel share a common BERT or XLM-R encoder, while each submodel has its own dedicated language-specific MLP. At training time, we iterate through the MTL-LS submodels in a round-robin fashion and alternate between training the MTL-LA submodel and training the chosen MTL-LS submodel. At test time, we can evaluate a test set with either the MTL-LA submodel or the MTL-LS submodel trained on the same language pair as the test set.

BiRNN We compared the above approaches to the BiRNN model from deepQuest (Ive et al., 2018). The BiRNN model uses an encoder-decoder architecture: it encodes both source and translation sentences independently using two bi-directional Recurrent Neural Networks (RNNs). The two resulting sentence representations are concatenated afterwards as the weighted sum of their word vectors, generated by an attention mechanism. For predictions at sentence-level, the weighted representation of the two input sentences is passed through a dense layer with sigmoid activation to generate the quality estimates. This is a light-weight variant of the black-box approaches above that does not rely on heavy pre-trained representations.

3 Data

This year two sentence-level QE tasks are available. For `Task 1` the participants are expected to predict DA-style human judgements (Graham et al., 2015), whereas the goal of `Task 2` is to estimate the post-editing effort (HTER). The data for `Task 1` includes six language pairs: Sinhala-English (Si-En), Nepalese-English (Ne-En), Estonian-English (Et-En), Romanian-English (Ro-En), English-German (En-De) and English-Chinese (En-Zh), where source sentences were extracted from Wikipedia articles. For `Task 2`, only English-Chinese and English-German are available. We also experimented with an additional dataset collected by IQT Labs in collaboration with the University of Sheffield. This is an Russian-English (Ru-En) dataset that contains a combination of Russian Reddit forums (75%) (using the Reddit API) and Russian WikiQuotes (25%). All MT outputs were generated by Transformer-based NMT systems (Vaswani et al., 2017). All datasets contain at least three DA judgements per MT segment by professional translators (0-100), with absolute quality scores standardised according to each annotator's mean and standard deviation. HTER labels were obtained by having professional translators fixing any errors in the translations, followed by using the TER[2] tool.

For each language pair the organisers provided training set (7000 sentences), development set (1000 sentences) and a blind test set (1000 sen-

[2] `http://www.cs.umd.edu/~snover/tercom/`

tences).

4 Settings

Glass-box To train proposed models, we used RandomForest from `sklearn` library[4] and XGBoost from `xgboost`[5] package. All input features are extracted from the NMT systems provided by the shared task's organisers. The number of features for `Probability` and `Dropout` groups does not depend on the parameters of the NMT systems and is equal to 3 and 4, respectively. The number of `Attention` features depends on the NMT system and is equal to the number of layers $\times$ the number of attention heads. We computed the sentence-level attention entropies in two ways: with and without the EOS token. For this reason, the total number of `Attention` features equals [Layers $\times$ Heads $\times$ 2]. This number is 96 for En-De/Zh and Et/Ro-En, and 192 for Si/Ne-En.

For our final experiments we combined the training (7000 sentences) and development (1000 sentences) sets, set a grid for the hyperparameters of our regression models and performed 5-fold cross-validation to choose the best hyperparameters.

Black-box We optimised our neural models with Adam (Kingma and Ba, 2015) and used the same learning rate ($1e^{-6}$) for all experiments. We trained each model on an Nvidia V100 GPU for 20 epochs with batch size of 8. Our final submission is an ensemble that combines the outputs from different variants of BASE and MTL QE models trained with different objective functions (mean squared error loss and huber loss) and contextualised encoder (BERT and XLM-R). We also included variants that use token-level log-probabilities from the NMT models as additional features. Each variant was trained 5 times with different random seeds. We used random forest (Breiman, 2001) to learn the ensemble. We set `n_estimators` to 500 and used the default values in `sklearn` for other hyperparameters.

[3]Results for the glass-box systems presented are slightly different from the official task results. The reason is that here we only show the results for the regression model trained with XGBoost, whereas both XGBoost and Random Forest models were submitted to the task.

[5]https://xgboost.readthedocs.io/en/latest/python/index.html

5 Results

In this section, we present and analyse the results for our submissions to `Task 1`. We provide a general comparison of the glass-box and black-box systems and also look at some specific aspects of their performance.

5.1 Overall Results

Table 1 shows the results of our submissions to `Task 1`. Besides Pearson correlation for each language pair, column `Avg` shows the average correlation across language pairs for each presented model, which corresponds to "multilingual" subtask from the organisers.[6] Note that although it was not required for the multilingual task to have a single QE system serving multiple languages, we build such systems for our multilingual experiments. The last column in Table 1 shows the number of parameters for each model. In the case of glass-box systems this corresponds to the number of features.[7]

The first group of systems in Table 1 corresponds to the glass-box approach including the unsupervised metrics and feature-based regression models (see Section 2.1).[8] Feature-based systems include models trained on a single language pair (Mono-LP), models based on multiple language pairs (Multi-LP) and an ensemble based on models trained with different amounts of data (see discussion below). The next group of systems corresponds to the black-box approach presented in Section 2.2. Besides the models based on pre-trained representations, we include BiRNN, a light-weight neural-based QE model.

The last two rows in Table 1 show the results of the baseline models prepared by the organisers and the Top #1 model. The baseline system is a neural predictor-estimator model trained with the default parameters described in OpenKiwi (Kepler et al., 2019). The predictor model was trained on the parallel data used to train the NMT models.

[6]The multilingual sub-task did not include Ru-En and it was not considered for the `Avg` column.

[7]As explained in Section 4, the number of features for the glass-box regression models changes depending on the language, as the corresponding NMT systems have different number of layers and attention heads. Thus, we have 199 features for Si/Ne-En, and 103 features for the rest of the language pairs.

[8]These experiments do not include Russian-English, as the corresponding NMT system is an ensemble and it is not evident how the glass-box features proposed by Fomicheva et al. (2020) should be extracted in this case.

Table 1: Results for `Task 1`: Pearson correlation coefficients between human DA scores and predicted values for WMT2020 test sets.[3] Avg is the average Pearson correlation across language pairs. Baseline and Top #1 results are taken from http://www.statmt.org/wmt20/quality-estimation-task_results.html. Results that are not significantly different from the Top #1 submission are marked in bold. We submitted results from ensemble (ML) to the multilingual subtask and results from ensemble (BL) to the per-language subtasks.

Below we summarize our observations:

General performance First, we observe that all our submitted systems outperform the baseline. In particular, the ensemble of models based on pre-trained contextualised representations achieves a very strong performance for some language pairs. It is either the top system or perform on par with the Top #1 submission, with no significant difference for Et-En, Ro-En, Si-En and En-De.[9]

Black-box models We also note that our XLM-R based models achieve a higher correlation with human judgements than the models built on top of BERT pre-trained representations, which can be related to the fact that XLM-R is a more powerful model with a much higher number of parameters. BiRNN, a light-weight neural-based QE system that does not use language model pre-training, shows lower correlation values, probably due to a relatively small amount of data available for training.

Glass-box models We note that glass-box systems perform competitively compared to some of the neural-based approaches. Interestingly, even the unsupervised submissions that rely only on the information extracted from the NMT models outperform the BiRNN and Predictor-Estimator neural-based QE systems, thus highlighting the benefit of this approach in a setting where a light-weight model is required (thus disallowing the use of BERT-style models fine-tuned on the QE task) and the amount of available training data is small. Regression-based models always improve on the individual unsupervised features for all language pairs (see Section 5.4 for discussion) and achieve comparable results to the BERT-based black-box systems.

5.2 Does model ensembling improve performance?

Ensembling multiple models is known to boost performance. We test whether this method improves the results for our systems. To produce ensemble for the glass-box approach, we computed an average of the predictions from the models trained with different amounts of data (see Section 5.5). As shown in Table 1, there is no difference between ensemble and individual models. For the black-box approach ensemble is produced by combining various types of models as described in Section 4. The ensemble of neural models provides a significant

[9] Here and in what follows we use the Hotelling-Williams test (Williams, 1959) to compute significance of the difference between dependent correlations with p-value < 0.05.

boost in performance at the cost of a very large number of parameters.

5.3 Multilingual models

For some MT production scenarios it is more convenient to have one multilingual QE model instead of having one model per language pair. We test how well the QE systems discussed in this paper perform in a multilingual setting. For the glass-box approach, we concatenated all training and development sets for En-De/Zh and Et/Ro-En together and trained a single model using this data. We exclude Si/Ne-En as we have a different number of features for these language pairs (see Section 4). Multilingual systems for the black-box approach are described in Section 2.2.

As can be seen from Table 1, both the glass-box and the black-box multilingual systems obtained results comparable to the models trained for individual language pairs. Thus, for the purposes of QE task both glass-box features and multilingual pre-trained representations generalise well across languages.

5.4 How does each group of features affect performance?

To investigate how each group of features affects performance of the glass-box models, we trained the models separately with different groups of features and their combinations, and computed Pearson correlation coefficients between predicted scores and DA. For our experiments we have three groups of features `Dropout`, `Probability` and `Attention`, all combinations of two of them and the combination of all three groups. We also show the correlation for some of the individual features: (i) translation probability (TP) as one of the simplest things we can extract from an NMT system; and (ii) two best performing unsupervised QE indicators from Fomicheva et al. (2020): dropout translation probability (D-TP) and dropout lexical similarity (D-Lex-Sim) (see Section 2.1).

As can be seen from Table 2, the best results among the individual groups of features are obtained for either `Dropout` features (Et/Ro/Si/Ne-En and En-Zh) or `Attention` features (En-De/Zh). The combination of all three groups of features and the combination of `Dropout` and `Attention` showed the best results for all language pairs.

Table 2 also shows the benefit of using supervision: combining features with XGBoost generally leads to a better correlation than directly using the best-performing individual QE indicators without any training ('Unsup' rows).

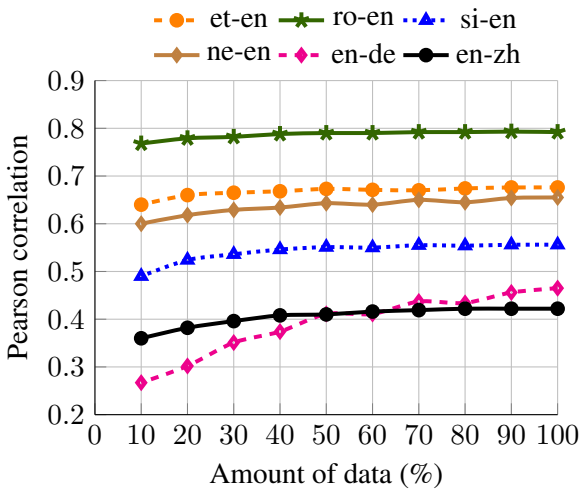

Figure 3: Pearson correlation coefficient between predicted values (glass-box models) of WMT2020 test sets and DA.

5.5 How many sentences do we need to train a QE system?

Here we investigate how the amount of available training data affects the performance of our systems. For this purpose, we randomly selected 10%, 20% ... 100% of the data and trained our models. We repeated data splitting and training of the models ten times; thus, we got 10 sets of predictions for each amount of data, we computed Pearson correlation coefficient between DA and predicted scores and took an average of these 10 correlation coefficients over each amount of data. As shown in Figure 3, the performance across the different amounts of training data with the glass-box models is stable for all language pairs except for En-De. Improvements over the best performing individual feature for each language pair can be obtained even with fairly small amounts of data.

Figure 4 shows the performance across different amounts of data for the BASE-BL black-box models. In this case, we observe larger improvements when more data is available for training. However, quite surprisingly, relatively high performance is achieved even with 5% and 10% of the data.

5.6 Task 2: HTER prediction

Besides experiments with DA labels, we used the same approach to train models with HTER data for En-De and En-Zh language pairs. Table 3 shows

		Et-En	Ro-En	Si-En	Ne-En	En-De	En-Zh
Type of features	Attention	0.519	0.722	0.455	0.583	0.382	0.353

		En-De	En-Zh
Glass-box	Mono-LP	0.601	0.605
	Ensemble	0.613	0.613
	Baseline	0.392	0.506
	Top #1	0.758	0.664

Table 3: Results for `Task 2` (sentence-level): Pearson correlation coefficient between HTER and predicted values for WMT2020 test set. The results of Baseline and the best models are taken from `http://www.statmt.org/wmt20/quality-estimation-task_results.html`.

Pearson correlation between the predictions and HTER scores for glass-box systems.[10] Interestingly, the glass-box approach performs more competitively when predicting HTER than when estimating DA scores, as the gap between our submission and the best performing system is smaller. Thus, this type of judgements might be easier to predict based on system-internal information from NMT models.

6 Conclusions

We presented glass-box and black-box models submitted to the WMT2020 QE shared task. Black-box models showed the results on a par with the top submissions. Glass-box methods achieve from moderate to strong linear correlation with human judgments and can be used as a light-weight and cost-effective alternative in a scenario where the NMT model is available. Besides that, we conducted experiments to test the performance of our QE systems in a multilingual setting. We showed that the performance of both approaches is comparable when training and predicting on the same language pair, and when training a single model to predict on multiple language pairs.

Abstract

This paper describes the submissions of the NiuTrans Team to the WMT 2020 Quality Estimation Shared Task (Specia et al., 2020). We participated in all tasks and all language pairs. We explored the combination of transfer learning, multi-task learning and model ensemble. Results on multiple tasks show that deep transformer machine translation models and multilingual pretraining methods significantly improve translation quality estimation performance. Our system achieved remarkable results in multiple level tasks, e.g., our submissions obtained the best results on all tracks in the sentence-level Direct Assessment task[1].

1 Introduction

Quality estimation (QE) evaluates the quality of machine translation output without human reference translations (Blatz et al., 2004). It has a wide range of applications in post-editing and quality control for machine translation.

We participated in all tasks and language pairs at the WMT 2020 QE shared task[2], including sentence-level Direct Assessment tasks, word and sentence-level post-editing effort tasks, and document-level QE tasks. We investigated transfer learning and ensemble methods using recently proposed multilingual pre-trained models (Devlin et al., 2019; Conneau et al., 2020) as well as deep transformer models (Wang et al., 2019a). Our main contributions are as follows:

- We apply multi-phase pretraining (Gururangan et al., 2020) methods under both high- and low-resource settings to QE tasks.
- We incorporate deep transformer NMT models into QE models.
- We propose a simple strategy to convert document-level tasks into word- and sentence-level tasks.
- We explore effective ensemble methods for both word- and sentence-level predictions.

Results on different level tasks show that our methods are very competitive. Our submissions achieved the best Pearson correlation on all language pairs of the sentence-level Direct Assessment task and the best results on English-Chinese post-editing effort tasks.

We present methods for the sentence-level Direct Assessment task in §2. Then in §3 and §4, we describe our approaches to post-editing tasks and document-level tasks, respectively. System ensemble methods are discussed in §5. We show the detail of our submissions and the results in §6. We conclude and discuss future work in §7.

2 Sentence-level Direct Assessment Task

The sentence-level Direct Assessment task is a new task where sentences are annotated with Direct Assessment (DA) scores by professional translators rather than post-editing labels. DA scores for each sentence are rated from 0 to 100, and participants are required to score sentences according to z-standardized DA scores. The DA task consists of seven tracks for different language pairs and one multilingual track. Submissions were evaluated in terms of Pearson's correlation metric for the DA prediction against human DA (z-standardized mean DA score, i.e., z-mean).

2.1 Datasets and Resources

This task contains 7K sentences for training and 1K sentences for development on each language pair,

[1]Our number of submissions exceeded the daily or total limit.

[2]http://www.statmt.org/wmt20/quality-estimation-task.html

Proceedings of the 5th Conference on Machine Translation (WMT), pages 1018–1023
Online, November 19–20, 2020.

including sentence scores and word probabilities from the NMT models. The organizer also provided parallel data used to train the NMT models except for Russian-English, ranging from high resource (En-De, En-Zh), medium resource (Ro-En), to low-resource (Et-En, Ne-En, Si-En).

In addition to the official data, we also used some multilingual pre-trained models for fine-tuning, including multilingual BERT[3] (mBERT) and XLM-RoBERTa[4] (XLM-R).

2.2 Unsupervised Quality Estimation

Our baseline system was built upon unsupervised quality estimation methods proposed by Fomicheva et al. (2020), which use out-of-box NMT models as sources of information for directly estimating translation quality. We utilized the output sentence probabilities from NMT models as indicators for QE tasks. Given the input sequence $\mathbf{x}$, suppose the decoder generates an output sequence $\mathbf{y} = y_1, \ldots, y_T$ of length T, the probability of generating $\mathbf{y}$ is factorized as:

$$p(\mathbf{y}|\mathbf{x}, \theta) = \prod_{t=1}^{T} p\left(y_t|\mathbf{y}_{<t}, \mathbf{x}, \theta\right) \quad (1)$$

where θ represents model parameters. The output probability distribution $p\left(y_t \mid \mathbf{y}_{<t}, \mathbf{x}, \theta\right)$ is produced by the decoder over the *softmax function*.

We considered the sequence-level translation probability normalized by length:

$$\text{TP} = \frac{1}{T} \sum_{t=1}^{T} \log p\left(y_t|\mathbf{y}_{<t}, \mathbf{x}, \theta\right) \quad (2)$$

And the probability generated from perturbed parameters with dropout, we performed N times inference and used the averaged output:

$$\text{D-TP} = \frac{1}{N} \sum_{n=1}^{N} \text{TP}_{\hat{\theta}^n} \quad (3)$$

2.3 Multi-phase Pretraining

Fine-tuning pre-trained language models have become the foundation of today's NLP (Devlin et al., 2019; Conneau et al., 2020). Recent advances in pre-trained multilingual language models lead to state-of-the-art results on QE tasks (Kim et al., 2019; Kepler et al., 2019a). Similar to Gururangan et al. (2020), we continued training multilingual pre-trained models in both domain- and task-adaptive manners.

Domain-adaptive pretraining uses a straightforward approach–we continue pretraining mBERT and XLM-R on the parallel corpora provided by the organizers, which is used to train the MT systems. Unlike the training data labeled with DA scores, the parallel data for different language pairs vary. The corpus of pre-trained language models also has the problem of data imbalance. In practice, we increased the training frequency of low-resource data.

Task-adaptive pretraining refers to pretraining on the unlabeled training set for a given task. Compared to domain-adaptive pretraining, it uses a far smaller corpus, but the data is much more task-relevant. We used the same models as the domain-adaptive pretraining.

2.4 Fine-tuning

Similar to previous work (Kepler et al., 2019a; Yankovskaya et al., 2019), we used models trained with the above methods as feature extractors for the sentence-level scoring tasks. We treated the scoring task as a regression task. Following standard practice, we added a separator token between source and target sentences and passed the pooled representation from the encoder to a task-specific feed-forward layer for classification. We used the z-standardized mean DA score as the ground truth and minimized the mean squared error during training.

3 Word and Sentence-Level Post-editing Effort Task

This task consists of the word- and sentence-level tracks to evaluate post-editing effort. The word-level tasks predicts OK or BAD tags in both source and target sequences. It evaluates the Matthews correlation coefficient[5] (MCC) for tags. The sentence-level task predicts HTER scores, which is the ratio between the number of edits needed and the reference translation length. It evaluates Pearson's correlation for the HTER prediction. There are two language pairs in both the word- and sentence-level tasks, including English-German (En-De) and English-Chinese (En-Zh).

[3] https://huggingface.co/bert-base-multilingual-cased

[4] https://github.com/facebookresearch/XLM

[5] https://en.wikipedia.org/wiki/Matthews_correlation_coefficient

3.1 Datasets and Resources

The labeled data consists of 7K sentences for training and 1K sentences for development for each language pair. We used the additional parallel data provided by the organizers to train predictors, containing about 20M En-Zh sentence pairs and 23M En-De sentence pairs after pre-processing with the NiuTrans SMT toolkit (Xiao et al., 2012). Pretrained language models include mBERT and XLM-R, were also used for Task 2.

3.2 Predictor-Estimator Models

The predictor-estimator architecture and its variants (Kim et al., 2017; Kepler et al., 2019b) had established state-of-the-art on WMT QE tasks. The system consists of a word prediction module (predictor) trained from additional large-scale parallel corpora and a quality estimation module (estimator) trained from quality-annotated data.

For the sentence-level tasks and target-side word-level tasks, we employed the official bi-RNN predictor-estimator trained with `OpenKiwi` (Kepler et al., 2019b) as the baseline. Similar to Wang et al. (2019b), we used NMT models trained with back-translation as predictors.

The original predictor and estimator use RNNs to encode the source and predict tags or scores. We also implemented two transformer-based predictors which replace the RNN with transformer (Vaswani et al., 2017) or deep transformer architectures (Wang et al., 2019a; Li et al., 2019). We compared different tokenizing strategies such as word segmentation and byte pair encoding (BPE) (Sennrich et al., 2016) for all language pairs.

3.3 Multi-task learning

The word- and sentence-level tasks are highly related to their annotations are commonly based on the HTER measure. We used a linear summation of sentence-level and target word-level objective losses as follows:

$$\mathcal{L} = \mathcal{L}_{mt.word} + \mathcal{L}_{mt.gap} + \mathcal{L}_{HTER} \quad (4)$$

where the components denote the loss of target-word, target-gap, and predictions for HTER score.

We also trained models using source sentence and origin/post-edited MT output to predict the source-side word level tags:

$$\mathcal{L}_{SRC} = \mathcal{L}_{src-mt} + \mathcal{L}_{src-pe} \quad (5)$$

4 Document-Level QE Task

This task aims to predict document-level quality scores as well as fine-grained annotations. Each document is annotated for translation errors with word span, severity, and error type[6]. Additionally, there are document-level scores (MQM scores) generated from the error annotations using the method proposed by Torrón and Koehn (2016). The annotation task evaluates F1 scores on the gold annotations. The scoring task evaluates the Pearson's correlation between the gold and predicted MQM scores.

4.1 Datasets and Resources

We also used 35M WMT14 En-Fr parallel data to train our predictors for the annotation task except for the official 1,448 En-Fr documents. For the scoring task, we used pre-trained language models, including mBERT and XLM-R.

4.2 Document-level Annotating Task

Following Kepler et al. (2019a), we treated the document-level annotation problem as a word-level task, with each sentence processed separately. We tokenized the training set and tagged each token with an OK/BAD tag. Specifically, each token was labeled as BAD if it contains any character in error spans. Besides token tags, we labeled a gap as BAD if a span begins and ends exactly in its borders. Otherwise, it was labeled as OK. During the test time, we mapped BAD tags to annotations in a single scheme: (a) continuous labels were merged into an error annotation; (b) individual labels were directly converted to error annotations. We ignored the severity information and always treated the error as the most frequent 'major'.

We adopt the predictor-estimator architecture for this task. We implemented our predictors with deep transformers with relative position representation. The settings for model training are described in (Hu et al., 2020). We also compared two tokenization schemes, including word-level tokenization and BPE. Similar to Task 2, we jointly trained our models with target-side word-level and word gap tasks.

4.3 Document-level Scoring Task

We treated the document-level scoring task as a sentence-level task with a simple mapping scheme.

[6] http://www.qt21.eu/mqm-definition/definition-2015-12-30.html

We also ignored all critical and minor errors, and thus the MQM score for each document is calculated by:

$$\text{MQM} = 100 \times (1 - \frac{W \times Count_{major}}{Count_{word}}) \quad (6)$$

where $Count_{major}$ and $Count_{word}$ are the count of major errors and total words, respectively. W denotes the weight of major errors, which is fixed at 5 in our experiments.

Then we score each sentence according to the number of errors it contains:

$$\text{Score}_{\text{sent}} = 100 - W \times Count_{major} \quad (7)$$

We applied the same fine-tuning strategies, as mentioned in Sec 2, to this task. During the test time, the count of errors was retrieved from the predicted score of all sentences. A document score is 0 if it has too many errors.

5 System Ensemble

In addition to training models for each task, we also explored effective ensemble methods to combine outputs for different level tasks.

5.1 Word-level ensemble

We used two approaches to ensemble word-level predictions for Task 2 and Task 3.

Voting-Based Ensemble. Voting is the easiest method to combine predictions from multiple models. We chose the label with the most votes for each token as the output.

Averaging-Based Ensemble. Similar to Kepler et al. (2019a), we used Powell's conjugate direction method to optimize the task metric (MCC or F1 score) and learn the weights of different systems on the development set.

5.2 Sentence-level ensemble

We averaged the predicted scores from multiple models associated with different weights. The weights were also learned on the development set using Powell's method. We removed outliers from the candidate pool to make the prediction more stable.

6 Experiments and Results

6.1 Task 1

Below we describe our systems for Task 1.

Unsupervised baseline. As described in §2, our baseline system leverages the output probabilities from NMT models to assess the sentence score. We performed 20 inference passes and set the dropout rate as 0.3 for all language pairs.

Pair	TP Score	D-TP Score
En-De	0.249	0.273 (+10%)
En-Zh	0.330	0.348 (+5%)
Ro-En	0.648	0.693 (+7%)
Et-En	0.497	0.562 (+13%)
Ne-En	0.431	0.490 (+14%)
Si-En	0.423	0.469 (+11%)
Ru-En	0.518	0.535 (+3%)

Table 1: Pearson (r) correlation between unsupervised methods and human DA judgements on the validation data for sentence-level DA tasks. We mark improvements of D-TP by percentage.

Pair	mBERT	XLM-R	Ensemble
En-De	0.516	0.555	0.562
En-Zh	0.512	0.533	0.551
Ro-En	0.888	0.911	0.917
Et-En	0.809	0.820	0.833
Ne-En	0.816	0.821	0.830
Si-En	0.607	0.670	0.698
Ru-En	0.728	0.796	0.816
Multilingual	-	-	0.732

Table 2: Pearson (r) correlation between pretraining methods and human DA judgements on the test data for sentence-level DA tasks. We only present the results of XLM-R-large for the second method.

Pretraining and fine-tuning. We experimented with different pre-trained models for multi-phase pretraining and fine-tuning. Specifically, we used three model settings, including mBERT-base cased (∼200M parameters), XLM-R-base (∼300M parameters), and XLM-R-large (∼600M parameters). Systems for the first six language pairs in Table 2 were pre-trained on the parallel data while the system for Ru-En was only trained on the task data. We combined predictions on the first six language pairs as the submission to the multilingual task.

As shown in Table 1, unsupervised QE indicators obtained competitive results using sequence-level probability from NMT models. Disturbing the model parameters improves the performance of all language pairs. We did not combine the predictions from unsupervised methods into our submissions.

Table 2 lists the results of the system ensemble

System	Target	Source
RNN-word	0.467	-
Transformer-word	0.511	-
Transformer-subword	0.542	0.292
Deep Transformer-subword	0.545	-
Ensemble	0.610	0.308

Table 3: Results of the English-Chinese post-editing task. 'word' denotes the system uses word-level tokenization.

System	Target	Source
RNN-word	0.395	-
Transformer-word	0.413	-
Transformer-subword	0.451	0.285
Ensemble	0.500	0.347

Table 4: Results of the English-German post-editing tasks.

with pretraining and fine-tuning. We combined predictions from 10 pre-trained models with three different settings: mBERT, XLM-R-base, and XLM-R-large. We only report the results with the highest Pearson (r) correlation on the test data. We observe that larger models consistently outperformed small ones for all language pairs. Besides, ensemble methods significantly improved the performance on the test set. It also shows that the quality estimation of high-resource languages performs far worse than low-resource languages.

6.2 Task 2

For En-Zh, we trained 5-10 single models for each setting: token-based bi-RNNs (RNN-Token), token-based transformer (Trans-Token), BPE-based transformer (Trans-BPE), and BPE-based deep transformer with 25 encoder layers (Deep Trans). For En-De, we created three systems using the same architectures as En-Zh except for the deep transformer. We applied the multi-task learning strategies to the target-side word-level and sentence-level tasks described as §3.

Table 3 shows the results on the English-Chinese word-level task. Deep transformer and BPE tokenization bring the most gains to both the target-side MCC. Results on the English-German task are listed in Table 4. It shows that our ensemble methods are effective in boosting performance across different tasks.

System	F1 Score	Pearson
Transformer-word	0.373	-
Transformer-subword	0.400	-
Deep Transformer	0.402	-
mBERT	-	0.446
XLM-R	-	0.489
Ensemble	0.418	0.494

Table 5: Results of the document-level tasks. The deep transformer model contains 24 encoder layers and 6 decoder layers.

6.3 Task 3

Table 5 shows the results obtained by three different models and the ensemble on the annotation task. BPE brings about 0.03 points improvements of F1 scores on both the validation and test sets. The system ensemble further pushes the score by about 0.02. Table 5 also lists the results of the scoring task. We report the results of two pretraining methods and their ensemble on the test data. XLM-R outperformed the mBERT model by 0.04 points in the Pearson correlation, while the ensemble brought a slight benefit.

7 Conclusion

This paper describes the submissions of the NiuTrans Team to the WMT 2020 QE task. We explored the combination of transfer learning, multi-task learning, and model ensemble. Different level tasks show that deep transformer NMT models and multilingual pretraining methods significantly boost QE models' performance.

Although our system achieved impressive results in all tasks and language pairs, there are still many problems. For instance, the translation quality estimation of low-resource languages performs much better than that of high-resource. It raises the concern of whether our model learns the evaluation criteria instead of memorizing data, as suggested in Sun et al. (2020). Besides, strong NMT models help quality estimation, but can we use QE models to improve NMT systems' learning? We plan to answer these questions in the future and promote the joint improvement of QE and NMT models.

Two-Phase Cross-Lingual Language Model Fine-Tuning for Machine Translation Quality Estimation

Dongjun Lee
Bering Lab, Republic of Korea
djlee@beringlab.com

Abstract

In this paper, we describe the Bering Lab's submission to the WMT 2020 Shared Task on Quality Estimation (QE). For word-level and sentence-level translation quality estimation, we fine-tune XLM-RoBERTa, the state-of-the-art cross-lingual language model, with a few additional parameters. Model training consists of two phases. We first pre-train our model on a huge artificially generated QE dataset, and then we fine-tune the model with a human-labeled dataset. When evaluated on the WMT 2020 English-German QE test set, our systems achieve the best result on the target-side of word-level QE and the second best results on the source-side of word-level QE and sentence-level QE among all submissions.

1 Introduction

Machine translation quality estimation (QE) is the task of estimating the quality of machine-translated (MT) output given just the source text at various granularity levels (word, sentence, and document) (Fonseca et al., 2019). Word-level QE can be divided into target-side and source-side tasks. On the target-side, the goal is to predict whether each word in the MT sentence is `OK` or `BAD` and whether there are missing words between each word. The goal on the source-side is to predict whether each word in the source sentence is correctly translated or not. On the other hand, sentence-level QE aims to predict the Human Translation Error Rate (HTER) (Snover et al., 2006) of the MT sentence, which measures the required amount of human editing to fix the MT sentence.

In this paper, we propose a cross-lingual language model fine-tuning approach with a few additional parameters for word-level and sentence-level QE. As a pre-trained cross-lingual language model, we use XLM-RoBERTa (XLM-R) (Conneau et al., 2019), which shows state-of-the-art performance for a wide range of cross-lingual transfer tasks. In addition, since labeling the QE dataset requires a large amount of human labor, we generate and utilize a huge artificial QE dataset to improve the performance of our model. Our contributions are summarized as follows.

- We propose an XLM-R-based neural network architecture for the QE. Our model can be jointly trained for both word-level and sentence-level QE.
- We generate a huge artificial QE dataset based on a parallel corpus with OpenNMT-py (Klein et al., 2017) and the TER tool (Snover et al., 2006).
- We train our model in two phases. First, we train our model with a huge artificially generated dataset. Then, we fine-tune the model with a human-labeled dataset.

In the experiment using the WMT 2020 English-German word-level QE test set, we achieve an MCC of 0.597 and 0.454 for the target-side and source-side, respectively, showing the best and second best performance among all submitted systems, respectively. For the sentence-level QE test set, we achieve a Pearson correlation of 0.723, which ranks second among all submissions.

2 Methodology

We fine-tune XLM-R (Conneau et al., 2019) with a few additional parameters for sentence-level and word-level QE as described in Figure 1. We train our model in two phases: 1) pre-training with a huge artificial dataset and 2) fine-tuning with a human-labeled dataset.

2.1 Input Representation

We follow the tokenization and input representation methods of XLM-R. A source sentence and

Proceedings of the 5th Conference on Machine Translation (WMT), pages 1024–1028

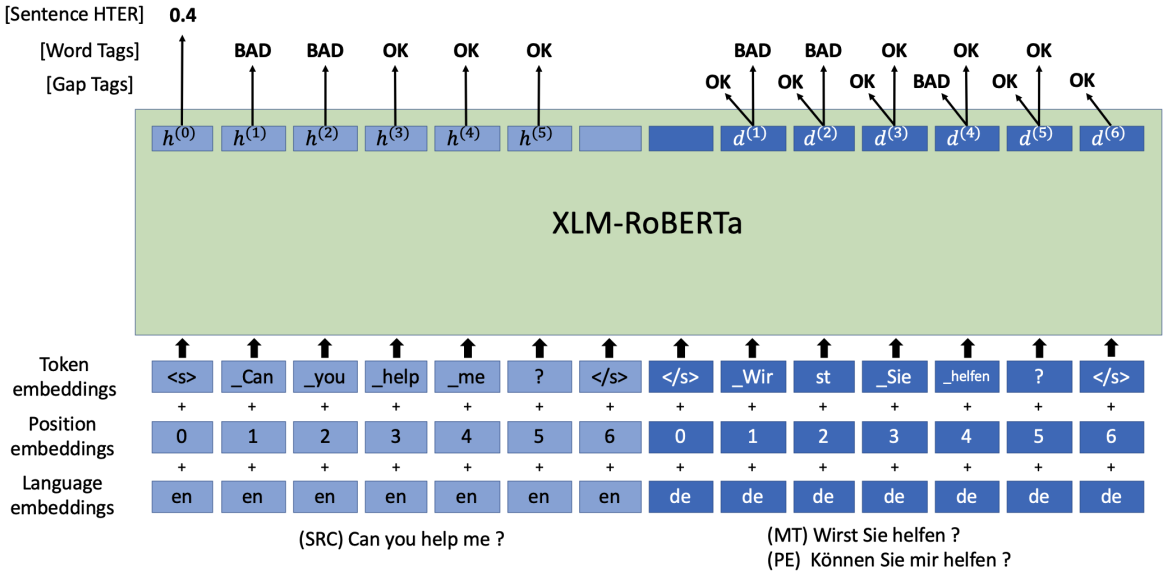

Figure 1: The XLM-R-based neural network architecture for word-level and sentence-level QE.

the corresponding MT sentence are tokenized with the same BPE model (Sennrich et al., 2016) that is trained based on shared vocabulary through languages. The input of the XLM-R model is a concatenated sequence of source tokens and MT tokens with special tokens (<s>, </s>) as follows:

<s> src_1, ..., $src_{|S|}$ </s> </s> mt_1, ..., $mt_{|T|}$ </s>

2.2 Sentence-level QE

For sentence-level QE, we use the final hidden vector $h^{(0)} \in \mathbb{R}^H$ of XML-R corresponding to the first input token (<s>) as the pooled representation. We use two linear layers with tanh activation to predict sentence-level HTER as follows:

$$r = W_s h^{(0)} + b_0 \quad (1)$$

$$y_{sent} = w_s^T tanh(r) + b_1 \quad (2)$$

where $W_s \in \mathbb{R}^{H \times H}$, $w_s \in \mathbb{R}^H$, $b_0 \in \mathbb{R}^H$ and $b_1 \in \mathbb{R}^1$ are trainable parameters and H is the dimension of hidden states.

The loss function L_{sent} is the mean squared error between y_{sent} and the true HTER $\hat{y}_{sent}$.

$$L_{sent} = MSE(y_{sent}, \hat{y}_{sent}) \quad (3)$$

2.3 Word-level QE

Word-level QE consists of two parts: the source-side and target-side. On the source-side, we predict whether each token in the source sentence is translated correctly or not. On the target-side, we predict whether each token in the MT sentence is OK or BAD, in addition to whether there are missing words between each word.

Source-side QE For source-side QE, we use the final hidden vector $h^{(i)} \in \mathbb{R}^H$ of XLM-R corresponding to each token in the source sentence. We introduce a linear layer and sigmoid activation to predict the probability that each token is BAD as follows:

$$P_{src}^{(i)} = sigmoid(w_o^T h^{(i)}), i \in (1, .., |S|) \quad (4)$$

where $w_o \in \mathbb{R}^H$ is a trainable parameter and $|S|$ is the number of tokens in the source sentence.

The loss function L_{src} is the binary cross entropy with an additional weight c for BAD examples as follows:

$$L_{src} = \frac{1}{|S|} \sum_{i=1}^{|S|} c\hat{y}_{src}^{(i)} \log P_{src}^{(i)} + (1 - \hat{y}_{src}^{(i)}) \log(1 - P_{src}^{(i)}) \quad (5)$$

Target-side QE For the target-side QE, we use the final hidden vector $d^{(i)} \in \mathbb{R}^H$ of XLM-R corresponding to each token in the MT sentence, including the last </s> token. We introduce two separate binary classification layers to predict the probability that each token in MT sentence is BAD as follows:

$$P_{tgt\_word}^{(i)} = sigmoid(w_w^T d^{(i)}), i \in (1, .., |T|) \quad (6)$$

and the probability that missing words exist before each token as follows:

$$P^{(i)}_{tgt\_gap} = sigmoid(w_g^T d^{(i)}), i \in (1, .., |T| + 1) \quad (7)$$

where $w_w, w_g \in \mathbb{R}^H$ are trainable parameters and $|T|$ is the number of tokens in the machine translated sentence.

The loss function for target-side QE L_{tgt} is the sum of the binary cross entropy for word L_{tgt_word} and gap L_{tgt_gap} that are defined in the same manner as Eq. (5).

$$L_{tgt} = L_{tgt\_word} + L_{tgt\_gap} \quad (8)$$

2.4 Pre-Training on Artificial Dataset

Building the Artificial Dataset Labeling data for QE requires the triplets of source sentences, machine-translated (MT) sentences, and human post-edited (PE) sentences. Since huge costs are required to achieve PE sentences, we use a parallel corpus that includes only source sentences and target sentences to build artificial triplets following the ideas from Negri et al. (2018).

First, we split the parallel corpus into a training set and test set. We train an NMT model with the training set and use the test set to generate artificial triplets. We generate MT sentences based on the trained NMT model and we use the target sentences of the parallel corpus as PE sentences. We repeat this process with different data splits to build huge artificial triplets. Finally, we use the TER tool[1] (Snover et al., 2006) to annotate sentence-level HTER scores and word-level tags for the MT sentences. We do not annotate source-side word-level tags in this work as it additionally requires word alignment between source sentences and MT sentences.

Pre-training QE Model We first pre-train our QE model with only the artificial dataset. In the pre-training step, we jointly train sentence-level QE and target-side word-level QE on a single model. The loss function for the pre-training step L_{pre_train} is the sum of the loss for sentence-level QE and target-side word-level QE.

$$L_{pre\_train} = L_{sent} + L_{tgt} \quad (9)$$

Since our artificial dataset does not include source-side word-level tags, we do not include the training objective for source-side word-level QE in the pre-training step.

[1] http://www.cs.umd.edu/~snover/tercom/

2.5 Fine-Tuning on Human-Labeled Dataset

After the pre-training, we fine-tune the model with only a human-labeled dataset. Unlike the pre-training step, each QE model (sentence-level, source-side and target-side of word-level) is trained separately in the fine-tuning step.

For the sentence-level and target-side of word-level QE models, all the parameters are initialized with trained weights from the pre-training step. However, since our pre-trained model does not include source-side word-level QE, we randomly initialize the weight of a source-side specific parameter (w_o in Eq. (4)) and the rest of the parameters are initialized with weights from the pre-trained model.

2.6 Ensemble

For the sentence-level ensemble, we average the HTER prediction of multiple models. For the word-level, we use the majority voting ensemble.

3 Experiments

3.1 Experimental Setup

We evaluate our model with WMT 2020 English-German QE dataset.[2] For the sentence-level QE evaluation, we use the Pearson correlation for sentence-level HTER prediction. For the word-level QE evaluation, we use the Matthews correlation coefficient (MCC) for both the target-side and source-side.

To generate an artificial dataset for pre-training (§2.4), we use the English-German parallel corpus provided by the shared task that consists of 23,440,059 pairs. We use 90% of the pairs to train a Transformer-based (Vaswani et al., 2017) NMT model with OpenNMT-py (Klein et al., 2017) and the rest of the pairs are used to generate artificial triplets. As a result of running the process five times with different data splits, we achieve 11,720,029 artificial triplets.

For the fine-tuning, we use only the official QE dataset that consists of 7,000 triplets as a human-labeled dataset.

3.2 Model Configuration

We use XLM-R-Large (Conneau et al., 2019) as a pre-trained cross-lingual language model. For pre-training with the artificial dataset, we use the Adam optimizer (Kingma and Ba, 2014) with a

IST and Unbabel	0.465	0.349
Baseline	0.358	0.266

Table 3: Top-5 and baseline systems from the official result for the word-level QE on the WMT 2020 English-German QE shared task.

learning rate of 5e-6, and a batch size of 8 for 2 epochs. Additionally, we use dropout (Hinton et al., 2012) with a rate of 0.1 for the regularization. For word-level QE, we use a weight of 3.0 on the `BAD` class (c). For fine-tuning with the human-labeled dataset, we follow the same hyperparameters as the pre-training step but for 5 epochs with early stopping. For the ensembling, we train five models with different random seeds.

3.3 Experimental Result

Table 1 shows the result of ablation analysis for sentence-level and word-level QE on the *dev* set. We conduct an ablation analysis of three aspects: 1) without an ensemble, 2) without pre-training with artificially generated dataset, 3) without fine-tuning with human-labeled dataset. When our model is trained with only the human-labeled dataset, Pearson correlation, target-side MCC and source-side MCC drop by 0.12, 0.11, and 0.09, respectively. This result demonstrates that pre-training with the artificial dataset significantly improves performance for both sentence-level and word-level QE. When our model is trained with only the artificial dataset, Pearson correlation and target side MCC drop by 0.29 and 0.21, respectively. This result shows that fine-tuning with a human-labeled dataset is essential for our performance.

Table 2 and 3 shows the official results for sentence-level and word-level QE for the WMT 2020 QE shared task. For both sentence-level and word-level QE, our systems significantly outperformed the official baseline systems (Kepler et al., 2019). Moreover, we achieve the best result on the target side of word-level QE among all submitted systems. We also achieve the second best

results on the source side of word-level QE and sentence-level QE.

4 Conclusion

This paper describes Bering Lab's submissions to the WMT 2020 QE shared task. We propose a two-phase cross-lingual language model fine-tuning approach for word-level and sentence-level translation quality estimation. The experimental results show that pre-training with an artificially generated dataset significantly improves performance for both tasks. Overall, our submitted systems achieve the best result on the target side of word-level QE and the second best results on the source side of word-level QE and the sentence-level QE among all submissions.

Abstract

We present the joint contribution of IST and Unbabel to the WMT 2020 Shared Task on Quality Estimation. Our team participated on all tracks (Direct Assessment, Post-Editing Effort, Document-Level), encompassing a total of 14 submissions. Our submitted systems were developed by extending the OpenKiwi framework to a transformer-based predictor-estimator architecture, and to cope with glass-box, uncertainty-based features coming from neural machine translation systems.

1 Introduction

Quality estimation (QE) is the task of evaluating a translation system's quality without access to reference translations (Blatz et al., 2004; Specia et al., 2018). This paper describes the joint contribution for Instituto Superior Técnico (IST) and Unbabel to the WMT20 Quality Estimation shared task, where systems were submitted to all three tasks: 1) sentence-level direct assessment; 2) word and sentence-level post-editing effort; and 3) document-level annotation and scoring.

Unbabel's participation in previous editions of the shared task (2016, 2017, 2019) used ensemble of strong individual systems, with varying architectures and hyper-parameters. While this strategy led to very strong results, large system ensembles are not a very practical solution, complicating model deployment and requiring expensive computation and memory usage. This year, in contrast, our focus was on simplicity: only single model systems were submitted and, in a few cases, an additional simple ensemble of the same model. Transfer learning on top of pretrained multilingual models was also used for avoiding manual pretraining for each language pair.

Last year's winning submission (Kepler et al., 2019a) combined strong individual systems built on top of the OpenKiwi framework (Kepler et al., 2019b) and pretrained Transformer models. We consolidated those changes with support for newly released pretrained models and packages and published a new version 2.0 of the OpenKiwi framework.[1] We trained and submitted single model systems in OpenKiwi for all tasks, beating all baselines by a large margin. Additionaly, we also used OpenKiwi with small adaptations to handle specific sources of information in Tasks 1 and 3.

Task 1, in particular, was introduced this year with Direct Assessment scores as targets. Further, it introduced the novelty of providing the trained NMT models that were used for producing the translations. Previously, only black-box QE was considered in the WMT Shared Task, as it is one of the main uses cases. With the availability of the NMT models, new glass-box approaches can be explored. Our best submitted systems drew inspiration from (Fomicheva et al., 2020) to leverage this information, improving in performance and robustness over a black-box approach.

Our main contributions are:

- We release the second version of OpenKiwi along with our submission, with a variety of new features, including the ability to use pretrained Transformer-based Language Models;
- We show that transfer learning techniques still perform well, by fine-tuning *XLM-Roberta* in a Predictor-Estimator architecture;
- We incorporate features extracted from the provided NMT models into our existing architectures and show that glass-box QE improves upon black-box approaches.

[1] The new version will be publicly available at https://github.com/unbabel/openkiwi.

Proceedings of the 5th Conference on Machine Translation (WMT), pages 1029–1036

2 Quality Estimation Tasks

This year's shared task edition comprised three tasks: 1) a newly introduced one for sentence-level direct assessment; 2) one for word and sentence-level post-editing effort; and 3) one for document-level. Refer to the Findings paper (Specia et al., 2020) for full descriptions.

Of noteworthy mention is that the NMT models for Tasks 1 and 2 where provided along with the data, which opened up the possibility of using glass-box approaches.

3 Implemented Systems

To avoid the complexity of ensemble of several systems, all our submitted systems consisted of a single model type. In addition to standard OpenKiwi 2.0 systems submitted to Tasks 1 and 2 (§3.1), we implemented two types of extensions on top of OpenKiwi, one for exploring glass-box approaches for Tasks 1 and 2 (§3.2), and one for handling document-level QE for Task 3 (§3.3).

3.1 Base OpenKiwi System

Given the success in doing transfer learning with pretrained Language Models in last year's shared task edition, we published support for them as part of the open source QE framework OpenKiwi in a new 2.0 version. BERT, XLM, and XLM-Roberta are currently supported via the `Transformers`[2] Python package (Wolf et al., 2019), which means different models can be easily used. For this year's shared task, we based all systems on this version of OpenKiwi and used pretrained XLM-Roberta models (Conneau et al., 2020), either `base` or `large` versions. We chose XLM-Roberta (called XLM-R from here on) instead of XLM, used in last year's best individual model, due to its reported state-of-the-art performance on downstream cross-lingual tasks and based on preliminary experiments.

The architecture follows the overall pattern introduced originally in the Predictor-Estimator model (Kim et al., 2017), comprising a "Feature Extractor" module with a "Quality Estimator" module on top. Figure 1 depicts this general architecture.

The Feature Extractor module consists of a pretrained XLM-R model and feature extraction methods on top, such that features for the target sentence, the target tokens, and the source tokens are returned separately. Source and target sentences

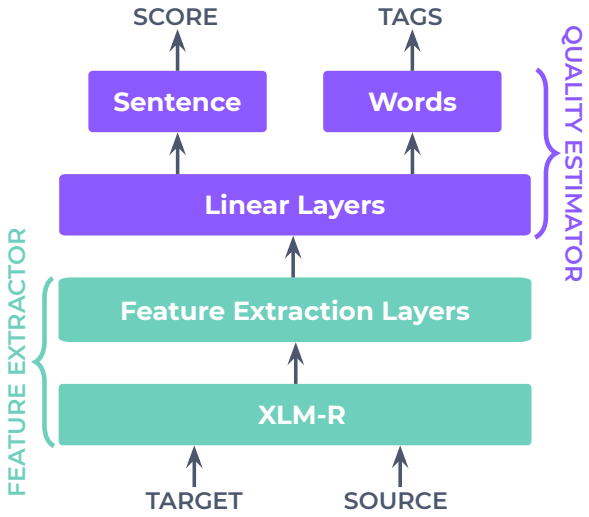

Figure 1: General architecture of the implemented OpenKiwi-based systems.

are passed as inputs in the format `<s> target </s> <s> source </s>`. Output features for tokens in the target sentence are averaged and then concatenated with the classifier token embedding (first `<s>` in the input), and returned as sentence features.[3]

For the Quality Estimator module we used linear layers instead of a bi-LSTM (as used by Kim et al. (2017)), since initial experiments showed similar performance. Additional linear layers were stacked on top for each output type: target words, target gaps, source words, and sentence regression.

For the plain OpenKiwi submissions we used the XLM-R `base` model and a Quality Estimator block with two linear layers. Hyper-parameter search was performed for each language pair and task[4] and submitted as a single model system to Tasks 1 and 2, and used as basis for the submission to Task 3. These systems will be referred to as OpenKiwi-base through the rest of the paper.

[2] https://github.com/huggingface/transformers

[3] Even though XLM-R was not trained on the Next Sentence Prediction objective (therefore not using the classification token in its original pretraining), preliminary experiments showed that concatenating inputs, average pooling, and using the classification token resulted in better performance compared to feeding source and target separately and extracting sentence features with other strategies (only pooled target, only the classifier token, classifier token + pooled source, and others).

[4] Hyper-parameters that were searched are: learning rate, dropout, number of warmup steps, and number of freeze steps.

3.2 Glass-Box QE

3.2.1 Glass-Box Features

Recent work on MT confidence estimation (Fomicheva et al., 2020) showed that useful information coming from an MT system, obtained as a by-product of translation, can be competitive with supervised black-box QE models in terms of correlation to human judgements of translation quality, in settings where the labeled data is scarce. The approach described in Fomicheva et al. (2020) requires access to the MT system that produced the translations (unlike the black-box regime). This year's new Task 1, and the fact it shares datasets with Task 2, allowed us to explore this approach on both tasks. In our work, we investigated how to combine the richness of this extra information coming from the provided Neural MT (NMT) system with the strength of state-of-the-art approaches to supervised QE.

To this end, we extract features (referred to as *glass-box features* henceforth) using the output probability distribution obtained from (i) a standard deterministic NMT and (ii) using uncertainty quantification. For (ii) we use Monte Carlo Dropout (Gal and Ghahramani, 2015) as a way of circumventing the miscalibration problem of Deep Neural Networks (Guo et al., 2017) and obtaining measures indicative of the model's uncertainty.

We obtain 7 different features for each sentence of each language-pair, the first 3 via (i) and the last 4 via (ii) (full details are in Fomicheva et al. (2020)):

- `TP` - sentence average of word translation probability
- `Softmax-Ent` - sentence average of softmax output distribution entropy
- `Sent-Std` - sentence standard deviation of word probabilities
- `D-TP` - average `TP` across $N (N = 30)$ stochastic forward-passes
- `D-Var` - variance of `TP` across N stochastic forward-passes
- `D-Combo` - combination of `D-TP` and `D-Var` defined by $1 - \texttt{D-TP}/\texttt{D-Var}$
- `D-Lex-Sim` - lexical similarity - measured by `METEOR` score (Banerjee and Lavie, 2005) - of MT output generated in different stochastic passes.

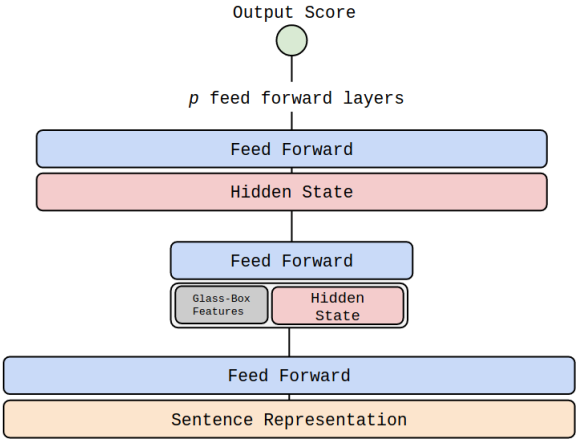

Figure 2: Architecture of the "Quality Estimator" module modified to include *glass-box features*.

Table 1 shows the correlation between each one of these features and human DAs for every language pair in Task 1. As expected, features obtained using uncertainty quantification consistently display higher correlations across all language-pairs, `D-TP` being the most effective for high and medium resource languages, and `D-Lex-Sim` for low resource languages.

3.2.2 Glass-box + Black-box Model

Different configurations were attempted in order to introduce the extracted glass-box features into the OpenKiwi system. The best empirical performance was observed with a simple method: we reduced the dimension of the pooled sentence features output from XLM-R by about five fold (onto `bottleneck_size`), creating a dimensional bottleneck and forcing a more compact sentence representation, and then concatenated the seven extracted glass-box features to this hidden state, followed by an expansion back to a higher dimensional state of `hidden_size`. The result is used as input feature for regression on the sentence score, employing `p` progressively smaller feed-forward layers (halving in size). A visualization of this process can be seen in Figure 2.

The glass-box features were individually normalized a priori, according to their mean and variance in the training dataset, allowing for their integration in the network's training in a scale-independent way.

Systems were trained for all language pairs in Tasks 1 and 2. XLM-R `large` was used instead of `base` version. We ran experiments with and without glass-box features. From here on we will

Table 1: Pearson correlation (r) between the employed *glass-box features* and human DA's for every language pair in Task 1 (validation set) - best results are in bold.

call KIWI-GLASS-BOX the system as described here, which was the one used for the official submissions, but for comparison we will also refer to KIWI-LARGE as the same system but without using the glass-box features.

Hyper-parameter search was performed over `p`, `bottleneck_size`, `hidden_size`, `warmup_steps` (number of warm up steps for optimizer), `freeze_steps` (number of steps for which XLM-R's weights are not updated) and `lr` (learning rate). The exact values can be found in Table 6 in Appendix A.

All submissions of KIWI-GLASS-BOX to Task 1 were created by simple linear ensembles, combining 5 of the models obtained through hyper-parameter search for each language pair. We used the validation set predictions of these 5 models to train a LASSO regression model. However since we do not possess labels for the test set, these ensembles were trained using k-fold cross-validation ($k = 10$) on the validation set.

3.3 Document-level QE

For Task 3 we submitted two systems, both of which are based on the general OpenKiwi architecture described in Section 3.1. The two systems differ only in the type of tags they predict, and the subsequent post-processing that is applied to these tags to obtain annotations and document-level MQM (Multidimensional Quality Metrics) scores. We submitted single systems that predict both tasks of document-level annotation and scoring.

The first system, henceforth referred to as KIWI-DOC, is OPENKIWI-BASE with additional data processing to convert between word- and sentence-level predictions, and document-level predictions. The data approach is the exact same as Kepler et al. (2019a). To obtain training data, annotations are converted to binary word-level tags (`OK` and `BAD` tags) and sentence-level MQM scores are computed from the annotations pertaining to the sentence. After training, document-level annotation predictions are obtained by the following heuristic: contiguous `BAD` tags in the word-level predictions are grouped into a single annotation span and are given the severity label `major`. Predicted document-level MQM scores are obtained by averaging predicted sentence-level MQM weighted by sentence-length (`regression`) or by direct computation from the predicted annotations using the MQM formula (`direct`).

The second system, KIWI-DOC-IOB, is a new contribution in which the task of annotating is approached as Named-entity recognition by using severity tags in IOB (Inside-Outside-Beginning) format.[5] This richer tag scheme addresses two types of information loss that occur in the approach taken for KIWI-DOC: the severity information is kept, and adjacent but disjoint annotations are not collapsed into single annotations during prediction.[6] This approach has the advantage that the predicted tag sequences can be converted to annotations directly by converting the token spans into character spans and using the predicted label as severity. The architecture of KIWI-DOC-IOB is identical to that of KIWI-DOC except that it is trained with a linear chain CRF[7] that enforces correctness of the IOB tag-sequence at prediction time[8].

For both systems we trained a final linear regression model that combines the two types of pre-

[5]The full label set is hence: `B-minor`, `I-minor`, `B-major`, `I-major`, `B-critical`, `I-critical`, and `O`.

[6]The two other types of information loss that were noted by Kepler et al. (2019a) are left unaddressed: tags are still defined at the token-level, and annotations consisting of multiple spans are still split into individual annotations.

[7]Each edge score is a single learned parameter that is independent of the input.

[8]During decoding, the edge scores corresponding to the impossible transitions are set manually to $-\infty$.

dicted MQM scores (`regression` and `direct`) with features derived from the tag-level predictions. We use the following additional features (when available[9]) computed over the document: the fraction of predicted tags corresponding to an error tag;[10] and the mean, variance, minimum, and maximum of the probability of the `BAD`. For simplicity we train the linear regression on the same training data as the systems. For each system, we perform search over all combinations of features, and choose the subset that gives the highest Pearson score on the validation set for that particular system.

4 Experimental Results

4.1 Task 1: Sentence-Level Direct Assessment

The results achieved over the validation set on all language pairs for Task 1 are shown in Table 2. We also include the best correlation achieved by any *glass-box feature* (denoted by BEST GB FEATURE), showing that indeed the proposed method allows for this rich information to complement and enhance the model's training, resulting in a performance increase when compared to model or GB-feature independently.

High resource language pair models (*En-De, En-Zh, Ru-En* benefit the most from the aid of NMT internal information, in particular English-German, where an increase of $\approx 4.5\%$ occurs; this might indicate the usefulness of incorporating nuanced information when sentence scores have less variability.

Scored test set predictions submitted during the development of this approach served as informative feedback, revealing the drop from validation to test performance to be smaller on KIWI-GLASS-BOX models when compared to KIWI-LARGE models, suggesting better generalization capabilities.

4.2 Task 2: Word and Sentence-Level Post-editing Effort

We trained OPENKIWI-BASE and KIWI-GLASS-BOX on all three subtasks at the same time: source tags, target tags, and sentence HTER. The best model was selected by the highest sum of the three metrics on the validation set. We used a single run of each of the two models to simultaneously predict the three outputs. The results can be seen in Table 3. Using the glass-box features provided a significant boost to the Pearson score, showing our strategy for sentence-level DA estimation performed well also when estimating sentence-level HTER.

Even though we only have a single model for all subtasks, our models outperformed the baselines by a large margin and performed very competitively in the test leaderboard (to cite Findings paper).

Table 3: Task 2 word and sentence-level results on the validation and test sets. Results for OPENKIWI-BASE and KIWI-GLASS-BOX were obtained from a single model trained by multi-tasking on the 3 different subtasks. (*) Baseline results on the validation set were not made available by the organizers.

System	Validation	Test
KIWI-DOC-`regression`	0.5146	0.4127
KIWI-DOC-`direct`	0.3131	0.3156
KIWI-DOC-`linear`	0.5635	0.4014
KIWI-DOC-IOB-`regression`	0.5731	**0.4746**
KIWI-DOC-IOB-`direct`	0.5483	0.3363
KIWI-DOC-IOB-`linear`	**0.6023**	0.4493

Table 4: Results of document-level (task 3) submissions for MQM scoring (Pearson). The results of KIWI-DOC and KIWI-DOC-IOB are for the same single model. For model selection during training we used the summed validation set Pearson of `direct` and `regression` to obtain a model that performs well in both methods.

System	Validation	Test
KIWI-DOC	**0.4934**	**0.4716**
KIWI-DOC-IOB	0.4016	0.4147

Table 5: Results of document-level (task 3) submissions for annotation (F1). For model selection during training we used validation set MCC for KIWI-DOC and validation set tagging F1 for KIWI-DOC-IOB.

a large drop in Pearson score from validation set to test set, in the range of 0.1-0.2,[11] which suggests that there is a difference in data distribution between the two sets. On the validation set, KIWI-DOC and KIWI-DOC-IOB obtain comparable Pearson correlation, albeit for different MQM methods. While both models perform comparably in the sentence score prediction (`regression`), the KIWI-DOC-IOB system clearly outperforms KIWI-DOC on the MQM scores that are computed directly from the predicted annotations (`direct`). The improvements made by linear regression on the validation set do not consistently translate to the test set. This suggests that our method of search over features for the linear regression is overly optimizing the performance to the validation data. It may also reflect our choice to train the linear model on system predictions on training data.

Table 5 shows the results for the annotation task. The best results are obtained by KIWI-DOC. Surprisingly, the strong scoring results of KIWI-DOC-IOB with `direct` (derived from predicted annotations) do not translate to good results on the annotation F1. The difference between the models is caused by the different trade-off between precision and recall: KIWI-DOC-IOB produces less annotations that are more precise, but KIWI-DOC catches much more errors.[12] The most likely cause for this is the more complex tag-set and constrained decoding of KIWI-DOC-IOB.

5 Conclusions

Our approach to this year's edition of the QE shared task was simplicity. Our submissions consisted of either single models, or simple ensembles of multiple runs of the same model. Moreover, we used multi-task models in Task 2, where a system was trained on all three possible outputs (target and source word level and sentence level). We implemented a new version of OpenKiwi and used it as our baseline. It significantly outperformed the official shared task baseline across the board, which was based on the previous version of OpenKiwi. Finally, we showed that having access to NMT models enables using glass-box approaches to QE, which in turn improves performance when used in

[11] The only exception is KIWI-DOC-IOB-`direct`, which performanced equally poorly on both.

[12] On the validation set KIWI-DOC-IOB predicted 2555 annotations, whereas KIWI-DOC predicted 4028 (the gold set has 5626 annotations). Extending the output message of the annotation evaluation script allowed us to further validate this hypothesis on the validation set: for KIWI-DOC-IOB precision/recall is 0.6287/0.3322; for KIWI-DOC precision/recall is 0.4549/0.6092.

combination with a black-box QE system.

Abstract

We introduce the TMUOU[1] submission for the WMT20 Quality Estimation Shared Task 1: Sentence-Level Direct Assessment. Our system is an ensemble model of four regression models based on XLM-RoBERTa with language tags. We ranked 4th in Pearson and 2nd in MAE and RMSE on a multilingual track.

1 Introduction

Quality Estimation (QE) is a task of estimating translation quality without reference sentences (Gandrabur and Foster, 2003; Blatz et al., 2004; Specia et al., 2018). Automatic evaluation metrics based on reference sentences, such as BLEU (Papineni et al., 2002), have contributed to improving translation quality on benchmark datasets. However, in situations where machine translation (MT) is actually used, these metrics are sometimes unable to assess the translation quality owing to the lack of reference sentences. The development of QE methods that are well correlated with manual evaluations enable users to decide whether to use the translation results as is, post-edit the results, or employ other machine translations.

At the Conference on Machine Translation (WMT), there have been conducted several QE-related competitions such as the QE task (Fonseca et al., 2019) for estimating post-edit rate HTER (Snover et al., 2006) and the QE as a Metric task (Ma et al., 2019) for relative evaluations of translation quality. This year, the WMT QE task held a new competition (Specia et al., 2020) on absolute evaluations of translation quality. In task 1, sentences are annotated with direct assessment (DA) scores as in the metrics task (Bojar et al., 2017).

We have been working on the metrics task with an approach that uses pre-trained sentence encoders (Shimanaka et al., 2018, 2019). Shimanaka et al. (2018) employed InferSent (Conneau et al., 2017), Quick-Thought (Logeswaran and Lee, 2018), and Universal Sentence Encoder (Cer et al., 2018) as encoders, and achieved the highest performance in all to-English language pairs of WMT18 metrics shared task (Ma et al., 2018). Subsequently, Shimanaka et al. (2019) employed BERT (Devlin et al., 2019) as an encoder to further improve the correlation with manual evaluations. In this study, we apply similar approaches to the QE task. However, to support both source and target languages, we employ XLM-RoBERTa[2] (Conneau et al., 2020), a pre-trained multilingual sentence encoder.

2 WMT20 QE Shared Task 1

In the WMT20 QE task 1 (Sentence-Level Direct Assessment), participants predict translation quality at the sentence level from pairs of source and MT output sentences. This task provides datasets for seven language pairs and sets up a multilingual track for a language-independent approach.

2.1 Datasets

Source sentences have been collected from Wikipedia for six language pairs: English–German (En-De), English–Chinese (Eh-Zh), Romanian–English (Ro-En), Estonian–English (Et-En), Nepalese–English (Ne-En), and Sinhala–English(Si-En). In addition, a combination of 75% Reddit data and 25% Wikipedia data for the Russian–English (Ru-En) language pair is provided. Organizers trained state-of-the-art neural MT models on each dataset using the fairseq toolkit (Ott et al., 2019) and generated MT output sentences.

Table 1: Examples of English-German dataset.

Three or more professional translators annotated DA scores in the range of 0-100 points for each pair of source and MT output sentences. These annotations are following the FLORES setup (Guzmán et al., 2019). The dataset consists of pairs of source and MT output sentences, z-standardized DA scores, and MT model score (log probabilities for words). Table 1 shows examples of the dataset. For each language pair, 7,000 training sets, 1,000 development sets, and 1,000 test sets are provided.

2.2 Baseline and Evaluation

The baseline system is a Predictor-Estimator model (Kim et al., 2017) implemented in OpenKiwi[3] (Kepler et al., 2019). The predictor is trained on a parallel corpus used to train the MT model, and predicts each target token from source and target contexts. And the estimator predicts the QE score from features produced by the predictor.

Participants are evaluated by Pearson's correlation metric (Pearson), mean absolute error (MAE), and root mean squared error (RMSE). A z-standardized DA score is used as a gold label.

3 TMUOU System

Our system is an ensemble model of four regression models based on XLM-RoBERTa (Conneau et al., 2020) with language tags. We first explain each base model in Section 3.1, and then introduce the ensemble model in Section 3.2. Finally, Section 3.3 describes the implementation details.

3.1 Base Models

Recently, the fine-tuning approach for masked language models (Devlin et al., 2019) has achieved the highest performance for many language understanding tasks (Wang et al., 2019). The BERT-based regression model (Shimanaka et al., 2019) also achieves high performance in the WMT metric task that estimates the DA score of translation quality (Bojar et al., 2017). We employ XLM-RoBERTa (Conneau et al., 2020), a multilingual masked language model, for this task to estimate the DA score of translation quality from pairs of source and MT output sentences.

E0 Model In this model, we fine-tune the XLM-RoBERTa in the normal way. We input sentence pairs into the model in the following format and use the special token `<s>` at the beginning of the first sentence to estimate the QE score: `<s> source </s> <s> MT output </s>`.

E0+LangTag Model To make it clear to the XLM-RoBERTa which language each sentence is in, we add a special token (LangTag) for language identification, such as `<en>`, at the beginning of each sentence. We have expanded the tokenizer and vocabulary and added the following eight LangTags: `<en> <et> <de> <ne> <ro> <ru> <si> <zh>`. An example of input to the model is as follows: `<s> <en> source </s> <s> <de> MT output </s>`.

E0+AVG Model Averaged token vector is as fruitful as the `<s>` vector at the beginning of the first sentence (Reimers and Gurevych, 2019). We concatenate the averaged token vector and the `<s>` vector to get richer information from sentence pairs.

E0+AVG+LangTag Model This model is a combination of the above models. As shown in Figure 1, we add LangTag at the beginning of each sentence and concatenate the `<s>` vector with the averaged token vector to estimate the QE score.

3.2 Ensemble Model

We ensemble four models described above to make prediction stable. A Gradient Boosting Tree (Fried-

man, 2001) is trained using k-fold cross-validation on the development set with the QE scores estimated by each base model as the features. In addition to the QE scores estimated by each base model, the features of the ensemble model also include the sum of MT model scores for each output word and a one-hot vector representing the language pair.

3.3 Implementation Details

We implemented all models based on the Hugging Face (Wolf et al., 2019) XLM-RoBERTa-large model.[4] The hyper parameters are as follows: batch size is 16, weight decay is 0.01, gradient clipping norm is 5.0, dropout for the attention layers and regression layer are 0.1, max epoch is 100. We use early stopping by Pearson metric on the dev sets with patience 5. We use Adam optimizer (Kingma and Ba, 2015) with warm up. The learning rate for the optimizer is $2e^{-5}$, and we gradually decrease the learning rate by a linear scheduler.

For the ensemble model, we trained gradient boosting regressor with least square loss implemented in scikit-learn (Pedregosa et al., 2011) with 10 folds cross-validation. The hyper parameters are as follows: the initial learning rate is 0.1, the number of estimators are 100, the subsample ratio is 1.0, the criterion is mean squared error with improvement score by Friedman, the minimum amount of sample split is 2, max depth of the tree is 3.

Table 3: Official results in ascending order of MAE.

4 Results

Table 2 shows the Pearson's correlation of each model on the development sets. Although there is no significant difference in the performance of the base models, the E0+AVG+LangTag model achieves higher performance in the majority of language pairs. The ensemble model achieves the highest performance in all language pairs. QE performance of to-English language pairs tends to be higher than that of from-English language pairs.

Table 3 presents the official results for a multilingual track. Participants are listed in ascending order of MAE. We submitted the ensemble model and ranked 4th in Pearson and 2nd in MAE and RMSE on a multilingual track.

5 Conclusions

We describe the TMUOU submission for the WMT20 Shared Task on Quality Estimation. Our system is an ensemble model based on XLM-RoBERTa, which takes into account averaged token vectors and language identifiers to improve performance. In the official evaluation, we ranked 4th in Pearson and 2nd in MAE and RMSE on a multilingual track.

Abstract

This paper describes the NICT Kyoto submission for the WMT'20 Quality Estimation (QE) shared task. We participated in *Task 2: Word and Sentence-level Post-editing Effort*, which involved Wikipedia data and two translation directions, namely English-to-German and English-to-Chinese. Our approach is based on multi-task fine-tuned cross-lingual language models (XLM), initially pre-trained and further domain-adapted through intermediate training using the translation language model (TLM) approach complemented with a novel self-supervised learning task which aim is to model errors inherent to machine translation outputs. Results obtained on both word and sentence-level QE show that the proposed intermediate training method is complementary to language model domain adaptation and outperforms the fine-tuning only approach.

1 Introduction

This paper presents the NICT Kyoto submission for the ninth edition of the quality estimation (QE) shared task organized at the fifth conference for machine translation (WMT'20). The goal of QE is to estimate the quality of machine translation (MT) output without using a translation reference. The system developed for the task and described in this paper is based on pre-trained cross-lingual language models (XLM) (Conneau and Lample, 2019), domain and task-adapted through intermediate training (Phang et al., 2018) and fine-tuned in a multi-task fashion for the sentence and word-level QE objectives.

It was shown during the QE shared task at WMT'19 (Fonseca et al., 2019) that pre-trained language models (LM) fine-tuned for QE reach state-of-the-art results at the levels of sentence and word following the predictor–estimator architecture (Kim et al., 2017) or using a fully end-to-end approach (Kepler et al., 2019; Kim et al., 2019; Zhou et al., 2019). However, fine-tuning pre-trained LMs is highly unstable when the dataset used for fine-tuning is small (Devlin et al., 2019; Zhang et al., 2020), which is usually the case for QE, as annotated datasets are scarce and expensive to produce, and WMT QE datasets are no exceptions (the shared task datasets are presented in Table 3). This fine-tuning instability might be due to neural network (NN) optimization difficulties or lack of generalization. (Mosbach et al., 2020)

To reduce fine-tuning instability of pre-trained LMs, Phang et al. (2018) introduced intermediate training, using large scale labeled data relevant to the target task in order to provide the pre-trained model with a transition step towards the final task. This approach is nonetheless limited by its reliance on annotated data for supervised learning. In our work, we propose a novel self-supervised intermediate training approach to adapt a pre-trained model to QE which does not rely on labelled data. We modify the popular masked LM objective to model simultaneously deletions and insertions in translations, two error types commonly observed in MT outputs.

Our approach is complementary to LM domain adaptation and we propose to conduct both tasks, i.e. domain and final task adaptation, jointly during intermediate training and prior to fine-tuning. More details about the intermediate training approach, including masked LM modifications and the datasets used, are presented in Section 2, followed by the QE task fine-tuning and evaluation in Section 3. Finally, a conclusion and future work are given in Section 4.

2 Intermediate Training

We describe in this Section the intermediate training process applied to the pre-trained LM used in our QE submission. This method could be applied

Proceedings of the 5th Conference on Machine Translation (WMT), pages 1042–1048

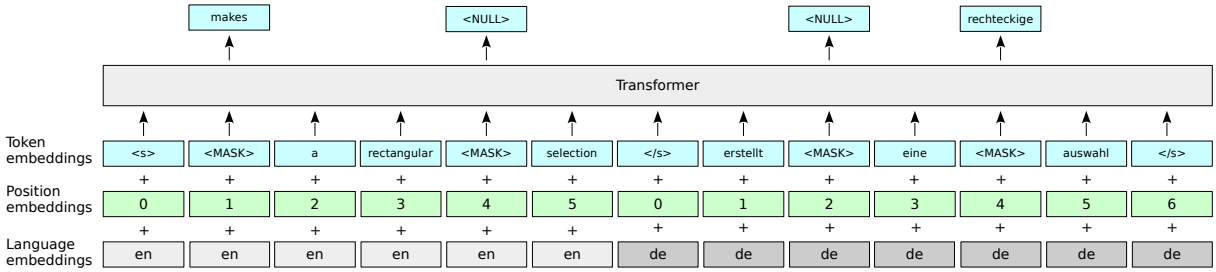

Figure 1: Intermediate self-supervised learning task based on the translation language model training objective of XLM with the addition of *NULL* tokens associated with randomly inserted *MASK* tokens.

to any pre-trained LM, but also when training a masked LM from scratch.

2.1 Approach Description

The fine-tuning of pre-trained LM has been applied to and has improved the performances of many natural language processing tasks such as grammatical sentence classification, paraphrases detection or textual entailment to name a few popular tasks. (Wang et al., 2018)

Some of the prevailing fine-tuned pretrained models studied in the literature are BERT (Devlin et al., 2019) and XLM (Conneau and Lample, 2019), among others. At the core of these approaches are similar LM techniques, using the sequentiality of languages to learn probabilities over sequences (X) of words (x_i, $i \in [0; n]$) as in $p(X) = \prod_{i=1}^{n} p(x_n|x_1, ..., x_n)$ (causal LM) or randomly masking some input tokens and learning to retrieve them based on both left and right contexts (masked LM). The masked LM approach introduced in BERT was extended in XLM to learn relations between translated sentences based on bilingual parallel corpora, integrating a new training objective called translation LM (TLM).

The TLM is particularly suited for QE, as it allows the model to learn bilingual context information when predicting masked tokens. However, fine-tuning pre-trained models was shown to be unstable with small datasets (Devlin et al., 2019), the reasons of this instability being studied recent work (Zhang et al., 2020; Mosbach et al., 2020). A proposed approach to reduce instability is to use a second stage pre-training step, between the initial LM training and the final task-oriented fine-tuning. It is based on a large amount of labeled data for a task related to the target objective. In addition to providing a *smooth* transition between initial pre-training and fine-tuning by coercing the model towards the final training objective, the intermediate step allows for domain adaptation when there is a domain mismatch between the datasets used for each training step. (Phang et al., 2018)

As a variant to the intermediate training approach, which originally makes use of labeled data, we propose a self-supervised intermediate step, alleviating the need for annotated data. We aim at combining both the domain adaptation advantage of continued training by using a dataset relevant to the final task, and target objective adaptation by modifying the masked LM approach used in the TLM model. More precisely, in addition to predicting the vocabulary masked in the input parallel sequences, we introduce *fake* masks for which a *null* token has to be predicted. This method forces the model to distinguish between missing words, which often occure in translated sentences when source words are not translated, and wrongly introduced words, similar to mistranslations when source words are wrongly translated. The proposed intermediate self-supervised learning task is illustrated in Figure 1.

2.2 Datasets and Tools

The domain and task adapted LMs used for our QE submissions are based on the pre-trained XLM model made available as a checkpoint in the HuggingFace Transformers library (Wolf et al., 2019), including 15 languages and trained using masked TLM.[1]. This model uses a sub-word vocabulary of 95k tokens shared between all languages, $1,024$ dimensions embeddings, learned language and position embeddings, 12 transformer blocks including 16 heads self-attention layers and $4,096$ dimensions feed-forward layers with Gaussian Error Linear Units (GELU) activation functions. The model has a total of approx. 249M parameters. The train-

ing objective is similar to the original TLM, except for an additional token in the vocabulary corresponding to the *null* token. We ran intermediate training for English–German and English–Chinese language pairs separately. The code used to conduct intermediate training was developed in-house on top of the HuggingFace Transformers library and written in PyTorch (Adam et al., 2017).

The datasets used for intermediate training are detailed in Table 1. We relied on the parallel data provided by the QE shared task organizers for English–German and English– Chinese, after selecting the most relevant sentence pairs based on their coverage of the source and MT output vocabulary extracted from the QE training, validation and test data. Using the test source and corresponding MT output is a limitation of the models presented in this paper, as a commercial QE system based on this method would require re-training when QE scores have to be produced for unseen data. However, our data filtering approach is still reliable without using the test set, as it is shown in Rubino and Sumita (2020). To remove noisy parallel sentences from the data used for intermediate training, we only kept sentence pairs containing a minimum of 3 tokens in the source and target sentences and with at least 40% of their tokens longer than 4 characters being in the QE vocabulary. In addition for the English–German LMs, we used the WikiMatrix corpus (Schwenk et al., 2019) made available by the WMT organizers for the news translation task.[2]

[2] http://data.statmt.org/wmt20/translation-task/WikiMatrix/

2.3 Training Procedure

Hyper-parameters specific to masked LMs, such as the amount of masked tokens per sequence, or more general to NNs, such as the optimizer learning-rate, have to be set prior to training. While the latter ones were suggested in previous work (Devlin et al., 2019; Conneau and Lample, 2019), we define and propose some values for the former ones in this paper. We trained a total of 8 masked LMs with variations in hyper-parameters, keeping checkpoints for each model based on the loss obtained on the validation set and at the end of every epoch. General and masked LM specific hyper-parameters are described in the following subsections and a summary of the trained masked LMs is presented in Table 2.

Note that we followed a token sampling similar to the one in XLM (Conneau and Lample, 2019), i.e., a first hyper-parameter is dedicated to the percentage of tokens to randomly select from a text sequence (noted *sample* in Table 2), a second hyper-parameter (noted *mask*) is allocated to the percentage of initially selected tokens which are replaced by a special *mask* token, a third hyper-parameter (noted *rand.*) is assigned to the percentage of initially selected tokens which are not replaced by *mask* but by tokens randomly sampled from the vocabulary. Finally, we introduce a fourth hyper-parameter, dedicated to the percentage of additional *mask* tokens introduced in a text sequence and corresponding to the *null* token.

2.3.1 General Hyper-parameters

All our masked LMs trained for the QE task used the *AdamW* optimizer (Loshchilov and Hutter, 2017) with the following parameters: $\beta_1 = 0.9$, $\beta_2 = 0.98$, $\epsilon = 1e^{-8}$ and weight decay set at $1e^{-8}$. The learning rate followed a linear schedule with a warm-up period during the first 4k steps to reach a maximum value of $5e^{-5}$ or $1e^{-4}$ depending on the model (as detailed in Table 2), then decayed until the model reached 100k steps. Depending on the model, the batch size was set to 32 or 64 with gradient accumulation set to 16 batches, respectively simulating batch sizes of 512 and $1,024$ pairs of source and target sequences.

2.3.2 Masked LM Hyper-parameters

We experimented with various percentages of tokens in pairs of text sequences to randomly sample initially, from 10% to 20%. From this selection rate, we made variations in how many were

id	sample	mask	rand.	fake	src	tgt	bsz	lr
1	15	80	50	0			32	$1e^{-4}$
2	15	25	95	0			32	$1e^{-4}$

Table 3: Number of sentences, source tokens, source types, MT tokens and MT types in the training, validation and test sets for the WMT'20 QE Task 2: Word and Sentence-level Post-editing Effort. Tokens and types denote words for English and German, and characters for Chinese, including numbers and punctuation marks.

replaced by the token *mask*: from 10% to 80%. From the remaining tokens initially sampled and not masked, from 50% to 100% of them were replaced by another token sampled randomly from the vocabulary. Finally, the remaining tokens initially sampled but not masked nor replaced were left unchanged. The percentage of fake masks (corresponding to the *null* token) was varied from 0% to 25%, additionally to the percentage of tokens randomly sampled intially during the first step. We also investigated the introduction of fake masks in the source or target sequences only, and in both source and target sequences.

3 QE Fine-tuning

The objective of fine-tuning masked LMs for QE is to predict sentence-level human translation edit rate (HTER) and word-level *good* and *bad* classes.[3] Note that in our models, for the target sequence word-level QE, we considered gaps between target words (missing translations) as part of the target sequence and did not use a loss nor a training objective specific to gaps.

3.1 Dataset

We used the training, validation and test sets released by the shared task organizers without any additional annotated data. Details about the official QE dataset are presented in Table 3.

3.2 Training Procedure

Our models presented in this paper were inspired by the approach of (Kim et al., 2019), however, we use XLM instead of BERT. We added two parallel outputs on top of XLM composed of parametrised linear layers. The first output layer corresponds to the word-level QE task, takes as input the word-level final hidden states given by XLM, and outputs word-level probabilities for the two classes (*OK* and *BAD*) using a softmax function. The second output layer corresponds to the sentence-level QE task, takes as input the final hidden state of the first token in a sentence pair (noted $<s>$ in Figure 1) given by XLM, and outputs a sequence-level probability using a sigmoid function. To compute the multi-task loss function, we first computed two loss functions separately, namely cross-entropy and mean squared error for the word-level and sentence-level QE respectively, based on the network predictions and the training gold labels. The two losses were then summed without weights to compose the final loss.

We chose the masked LMs to fine-tune based on the validation (presented in Table 1) loss and at the end of epoch 5 for English–German and epoch 10 for English–Chinese (the latter models were faster to train due to the smaller LM intermediate training data size). Thus, 2 checkpoints were kept for each of the 8 models presented in Table 2. In order to find good hyper-parameters to fine-tune the masked LMs for QE and because the QE datasets are relatively small, we conducted a grid-search among

[3] More details about the WMT'20 QE Task 2: Word and Sentence-level Post-editing Effort are available at http://www.statmt.org/wmt20/quality-estimation-task.html

Table 4: Sentence-level predicted post-editing effort on the official WMT'20 QE validation set. The *id* column refers to the Model ID as presented in Table 2. The *id* 0 denotes the out-of-the-box XLM checkpoint without domain or task adaptation through intermediate training and without QE fine-tuning. The *id* 0* denotes the QE fine-tuned XLM checkpoint without domain or task adaptation through intermediate training.

the following hyper-parameters: masked LM and output layer learning rates, dropout rate, using or not class weights for the softmax function, and finally the decay rate applied to the discriminative fine-tuning approach (Howard and Ruder, 2018). During hyper-parameter search and training of the final models, the batch size was set to 64 sequence pairs and the learning rate was warmed-up linearly for 200 steps. The remaining hyper-parameters were set to values identical to the ones presented in Section 2.3.

3.3 Evaluation

We present in this Section the results obtained during our experiments, first on the official validation set and then on the official test set, based on the masked LMs presented in Table 2. For the sentence-level post-editing effort prediction, the official primary metric was the Pearson correlation coefficient (r) and two supplementary metrics were used: mean absolute error (MAE) and root mean squared error (RMSE). For the word-level binary classes prediction, the official primary metric was the Matthews correlation coefficient (MCC) and supplementary F-measures for the *OK* class and for the *BAD* class were used. The word-level evaluation was conducted on source and target sequences separately. The results obtained on the sentence-level task are presented in Table 4 and the results obtained on the word-leve task are presented in Table 5. For the latter, we present a single F-score for both *OK* and *BAD* classes by multiplying individual F-scores (similarily to the *F1 mult* score used during the WMT'19 QE task (Fonseca et al., 2019)).

Results obtained at the sentence-level (Table 4) show that both domain adaptation and fake-masking are useful as an intermediate training task prior to QE fine-tuning. The best results according to Pearson's r are reached by the model #6 for the two language pairs. This model has an equal amount of masked and randomly replaced tokens, and fake masks are inserted in target sequences only. The same model reaches the best results for the EN–ZH language pair for all the metrics while there is no best performing model on all metrics for the EN–DE pair. When comparing the models obtained with configurations #1 and #5, which differ mainly on the introduction of fake masks for the latter, best performances are reached by model #5 as indicated by the three metrics, showing that fake masking is helpful in predicting sentence-level post-editing effort. However, the batch size and the learning rate also differ for these two configurations. A more consistant ablation study allowing for a fair comparison between configurations with and without fake masking is presented in Rubino and Sumita (2020).

Experiments on the word-level results (Table 5) show that introducing fake-masks is useful for the EN–DE language pair on both source and target text sequences, as the best performances according to both metrics are reached by models #5, #7 and #8. The introduction of fake masks in model #5, compared to model #1 which does not have fake masks, show that this method is helpful for this language pair at predicting word-level quality estimation. However, this is not the case on the source side for EN–ZH, where model #1 reaches the best results in terms of MCC and F1. This model does not involve fake-masking but only domain adaptation. On the target side, however, the best results according to both metrics are reached by models involving fake-masking, namly models #3, #6 and #7 with 0.566 MCC and 0.604 F1.

Our final submission to the shared task was composed of an ensemble of all the checkpoints for all the models, i.e. 32 models per language pair and QE task (8 pre-trained models, fine-tuning checkpoints based on validation loss, primary metric score and best epoch). We present in Table 6 and Table 7 the official results obtained by our final submission ensembles on the test set as reported by the shared task organizers on the sentence-level

and word-level tasks respectively.

4 Conclusion

We have presented in this paper the NICT Kyoto submission for the WMT'20 QE shared task on predicting post-editing effort at the sentence and word-level. Our submissions consisted of ensembles of several fine-tuned masked LMs, pre-trained using the translation LM objective, domain and task adapted in a self-supervised fashion using domain-relevant data and a modified masking approach during intermediate training.

This novel intermediate training objective allows for a *smooth* transition from a pre-trained masked LM towards the final QE task without requiring annotated data. We have shown empirically that both domain and task adaptation reach good results compared to out-of-the-box pre-trained models and compared to fine-tuning only. Our final submissions were ranked among the top systems both at the sentence and word-level for two language pairs.

Abstract

This paper presents the team TransQuest's participation in Sentence-Level Direct Assessment shared task in WMT 2020. We introduce a simple QE framework based on cross-lingual transformers, and we use it to implement and evaluate two different neural architectures. The proposed methods achieve state-of-the-art results surpassing the results obtained by OpenKiwi, the baseline used in the shared task. We further fine tune the QE framework by performing ensemble and data augmentation. Our approach is the winning solution in all of the language pairs according to the WMT 2020 official results.

1 Introduction

The goal of quality estimation (QE) systems is to determine the quality of a translation without having access to a reference translation. This makes it very useful in translation workflows where it can be used to determine whether an automatically translated sentence is good enough to be used for a given purpose, or if it needs to be shown to a human translator for translation from scratch or postediting (Kepler et al., 2019). Quality estimation can be done at different levels: document level, sentence level and word level (Ive et al., 2018). This paper presents TransQuest, a sentence-level quality estimation framework which is the winning solution in all the language pairs in the WMT 2020 Sentence-Level Direct Assessment shared task (Specia et al., 2020).

In the past, high preforming quality estimation systems such as QuEst (Specia et al., 2013) and QuEst++ (Specia et al., 2015) were heavily dependent on linguistic processing and feature engineering. These features were fed into traditional machine-learning algorithms like support vector regression and randomised decision trees (Specia et al., 2013), which then determined the quality of a translation. Even though, these approaches provide good results, they are no longer the state of the art, being replaced in recent years by neural-based QE systems which usually rely on little or no linguistic processing. For example the best-performing system at the WMT 2017 shared task on QE was POSTECH, which is purely neural and does not rely on feature engineering at all (Kim et al., 2017).

In order to achieve high results, approaches such as POSTECH require extensive pre-training, which means they depend on large parallel data and are computationally intensive (Ive et al., 2018). TransQuest, our QE framework removes this dependency on large parallel data by using crosslingual embeddings (Ranasinghe et al., 2020) that are already fine-tuned to reflect properties between languages (Ruder et al., 2019). Ranasinghe et al. (2020) show that by using them, TransQuest eases the burden of having complex neural network architectures, which in turn entails a reduction of the computational resources. That paper also shows that TransQuest performs well in transfer learning settings where it can be trained on language pairs for which we have resources and applied successfully on less resourced language pairs.

The remainder of the paper is structured as follows. The dataset used in the competition is briefly discussed in Section 2. In Section 3 we present the TransQuest framework and the methodology employed to train it. This is followed by the evaluation results and their discussion in Section 4. The paper finishes with conclusions and ideas for future research directions.

2 Dataset

The dataset for the Sentence-Level Direct Assessment shared task is composed of data

Proceedings of the 5th Conference on Machine Translation (WMT), pages 1049–1055

extracted from Wikipedia for six language pairs, consisting of high-resource languages English-German (En-De) and English-Chinese (En-Zh), medium-resource languages Romanian-English (Ro-En) and Estonian-English (Et-En), and low-resource languages Sinhala-English (Si-En) and Nepalese-English (Ne-En), as well as a a Russian-English (Ru-En) dataset which combines articles from Wikipedia and Reddit (Specia et al., 2020). Each language pair has 7,000 sentence pairs in the training set, 1,000 sentence pairs in the development set and another 1,000 sentence pairs in the testing set. Each translation was rated with a score between 0 and 100 according to the perceived translation quality by at least three translators (Fomicheva et al., 2020). The DA scores were standardised using the z-score. The quality estimation systems have to predict the mean DA z-scores of the test sentence pairs (Specia et al., 2020).

3 Methodology

This section presents the methodology used to develop our quality estimation methods. Our methodology is based on TransQuest our recently introduced QE framework (Ranasinghe et al., 2020). We first briefly describe the neural network architectures TransQuest proposed, followed by the training details. More details about the framework can be found in (Ranasinghe et al., 2020).

3.1 Neural Network Architectures

The *TransQuest* framework that is used to implement the two architectures described here relies on the XLM-R transformer model (Conneau et al., 2020) to derive the representations of the input sentences (Ranasinghe et al., 2020). The XLM-R transformer model takes a sequence of no more than 512 tokens as input, and outputs the representation of the sequence. The first token of the sequence is always [CLS] which contains the special embedding to represent the whole sequence, followed by embeddings acquired for each word in the sequence. As shown below, proposed neural network architectures of TransQuest can utilise both the embedding for the [CLS] token and the embeddings generated for each word (Ranasinghe et al., 2020). The output of the transformer (or transformers for **SiameseTransQuest** described below), is fed into a simple output layer which is used to estimate the quality of translation. The way the XLM-R transformer is used and the output layer are different in the two instantiations of the framework. We describe each of them below. The fact that TransQuest does not rely on a complex output layer makes training its architectures much less computationally intensive than alternative solutions. The *TransQuest* framework is open-source, which means researchers can easily propose alternative architectures to the ones TransQuest presents (Ranasinghe et al., 2020).

Both neural network architectures presented below use the pre-trained XLM-R models released by HuggingFace's model repository (Wolf et al., 2019). There are two versions of the pre-trained XLM-R models named XLM-R-base and XLM-R-large. Both of these XLM-R models cover 104 languages (Conneau et al., 2020), potentially making it very useful to estimate the translation quality for a large number of language pairs.

TransQuest implements two different neural network architectures (Ranasinghe et al., 2020) to perform sentence-level translation quality estimation as described below. The architectures are presented in Figure 1.

1. **MonoTransQuest** (**MTransQuest**): The first architecture proposed uses a single XLM-R transformer model and is shown in Figure 1a. The input of this model is a concatenation of the original sentence and its translation, separated by the [SEP] token. TransQuest proposes three pooling strategies for the output of the transformer model: using the output of the [CLS] token (`CLS`-strategy); computing the mean of all output vectors of the input words (`MEAN`-strategy); and computing a max-over-time of the output vectors of the input words (`MAX`-strategy) (Ranasinghe et al., 2020). The output of the pooling strategy is used as the input of a softmax layer that predicts the quality score of the translation. TransQuest used mean-squared-error loss as the objective function (Ranasinghe et al., 2020). Similar to Ranasinghe et al. (2020), the early experiments we carried out demonstrated that the `CLS`-strategy leads to better results than the other two strategies for this architecture. Therefore, we used the embedding of the [CLS] token as the input of a softmax layer.

2. **SiameseTransQuest** (**STransQuest**): The second approach proposed in TransQuest

relies on the Siamese architecture depicted in Figure 1b which has shown promising results in monolingual semantic textual similarity tasks (Reimers and Gurevych, 2019; Ranasinghe et al., 2019). For this, we fed the original text and the translation into two separate XLM-R transformer models. Similarly to the previous architecture, we experimented with the same three pooling strategies for the outputs of the transformer models (Ranasinghe et al., 2020). TransQuest then calculates the cosine similarity between the two outputs of the pooling strategy. TransQuest used mean-squared-error loss as the objective function. Similar to Ranasinghe et al. (2020) in the initial experiments we carried out with this architecture the `MEAN`-strategy showed better results than the other two strategies. For this reason, we used the `MEAN`-strategy for our experiments. Therefore, cosine similarity is calculated between the mean of all output vectors of the input words produced by each transformer.

3.2 Training Details

We used the same set of configurations suggested in Ranasinghe et al. (2020) for all the language pairs evaluated in this paper in order to ensure consistency between all the languages. This also provides a good starting configuration for researchers who intend to use TransQuest on a new language pair. In both architectures, we used a batch-size of eight, Adam optimiser with learning rate $2e{-}5$, and a linear learning rate warm-up over 10% of the training data. The models were trained using only training data. Furthermore, they were evaluated while training using an evaluation set that had one fifth of the rows in training data. We performed early stopping if the evaluation loss did not improve over ten evaluation rounds. All of the models were trained for three epochs. For some of the experiments, we used an Nvidia Tesla K80 GPU, whilst for others we used an Nvidia Tesla T4 GPU. This was purely based on the availability of the hardware and it was not a methodological decision.

3.3 Implementation Details

The TransQuest framework was implemented using Python 3.7 and PyTorch 1.5.0. To integrate the functionalities of the transformers we used the version 3.0.0 of the HuggingFace's Transformers library. The implemented framework is available on GitHub[1].

4 Evaluation, Results and Discussion

This section presents the evaluation results of our architectures and the fine tuning strategies that can be used to improve the results. We first evaluate the TransQuest framework with the default setting (Section 4.1). Next we evaluate an ensemble setting of TransQuest in Section 4.2. We finally assess the performance of TransQuest with augmented data. We conclude the section with a discussion of the results.

The evaluation metric used was the Pearson correlation (r) between the predictions and the gold standard from the test set, which is the most commonly used evaluation metric in WMT quality estimation shared tasks (Specia et al., 2018; Fonseca et al., 2019). We report the Pearson correlation values that we obtained from CodaLab, the hosting platform of the WMT 2020 QE shared task. As a baseline we compare our results with the performance of OpenKiwi as reported by the task organisers (Specia et al., 2020).

4.1 TransQuest with Default settings

The first evaluation we carried out was for the default configurations of the TransQuest framework where we used the training set of each language to build a quality estimation model using XLM-R-large transformer model and we evaluated it on a test set from the same language.

The results for each language with *default* settings are shown in row I of Table 1. The results indicate that both architectures proposed in *TransQuest* outperform the baseline, OpenKiwi, in all the language pairs. From the two architectures, *MTransQuest* performs slightly better than *STransQuest*.

As shown in Table 1, *MTransQuest* gained $\approx$ 0.2-0.3 Pearson correlation boost over OpenKiwi in all the language pairs. Additionally, *MTransQuest* achieves $\approx$ 0.4 Pearson correlation boost over OpenKiwi in the low-resource language pair Ne-En.

Table 1: Pearson (r) correlation between *TransQuest* algorithm predictions and human DA judgments. Best results for each language (any method) are marked in bold. Rows I, II, III and IV indicate the different settings of *TransQuest*, explained in Sections 4.1-4.3. OpenKiwi baseline results are in Row V.

4.2 TransQuest with Ensemble

Transformers have been proven to provide better results when experimented with ensemble techniques (Xu et al., 2020). In order to improve the results of TransQuest we too followed an ensemble approach which consisted of two steps. We conducted these steps for both architectures in TransQuest.

1. We train TransQuest using the pre-trained XLM-R-base transformer model instead of the XLM-R-large transformer model in the TransQuest default setting. We report the results from the two architectures from this step in row II of Table 1 as MTransQuest-base and STransQuest-base.
2. We perform a weighted average ensemble for the output of the default setting and the output we obtained from step 1. We experimented on weights 0.8:0.2, 0.6:0.4, 0.5:0.5 on the output of the default setting and output from the step 1 respectively. Since the results we got from XLM-R-base transformer model are slightly worse than the results we got from default setting we did not consider the weight combinations that gives higher weight to XLM-R-base transformer model results. We obtained best results when we used the weights 0.8:0.2. We report the results from the two architectures from this step in row III of Table 1 as MTransQuest ⊗ and STransQuest ⊗.

As shown in Table 1 both architectures in TransQuest with ensemble setting gained ≈ 0.01-0.02 Pearson correlation boost over the default settings for all the language pairs.

4.3 TransQuest with Data Augmentation

All of the languages had 7,000 training instances that we used in the above mentioned settings in TransQuest. To experiment how TransQuest performs with more data, we trained TransQuest on a data augmented setting. Alongside the training, development and testing datasets, the shared task organisers also provided the parallel sentences which were used to train the neural machine translation system in each language. In the data augmentation setting, we added the sentence pairs from that neural machine translation system training file to training dataset we used to train TransQuest. In order to find the best setting for the data augmentation we experimented with adding 1000, 2000, 3000, up to 5000 sentence pairs randomly. Since the ensemble setting performed better than the default setting of TransQuest, we conducted this data augmentation experiment on the ensemble setting. We assumed that the sentence pairs added from the neural machine translation system training file have maximum translation quality.

Up to 2000 sentence pairs the results continued to get better. However, adding more than 2000 sentence pairs did not improve the results. We did not experiment with adding any further than 5000 sentence pairs to the training set since the timeline of the competition was tight. We were also aware that adding more sentence pairs with the maximum translation quality to the training file will make it imbalance and affect the performance of the machine learning models negatively. We report the results from the two architectures from this step in row IV of Table 1 as MTransQuest ⊗-Aug and STransQuest ⊗-Aug.

This setting provided the best results for both architectures in TransQuest for all of the language pairs. As shown in Table 1 both architectures in TransQuest with the data augmentation setting gained ≈ 0.01-0.09 Pearson correlation boost over the default settings for all the language pairs. Additionally, *MTransQuest ⊗-Aug* achieves ≈ 0.09 Pearson correlation boost over default MTransQuest in the high-resource language pair En-De.

4.4 Error analysis

In an attempt to better understand the performance and limitations of *TransQuest* we carried out an error analysis on the results obtained on Romanian - English and Sinhala - English. The choice of language pairs we analysed was determined by the availability of native speakers to perform this analysis. We focused on the cases where the difference between the predicted score and expected score was the greatest. This included both cases where the predicted score was underestimated and overestimated.

Analysis of the results does not reveal very clear patterns. The largest number of errors seem to be caused by the presence of named entities in the source sentences. In some cases these entities are mishandled during the translation. The resulting sentences are usually syntactically correct, but semantically odd. Typical examples are *RO: În urmă explorărilor Căpitanului James Cook, Australia și Noua Zeelandă au devenit ținte ale colonialismului britanic. (As a result of Captain James Cook's explorations, Australia and New Zealand have become the targets of British colonialism.) - EN: Captain James Cook, Australia and New Zealand have finally become the targets of British colonialism.* (expected: -1.2360, predicted: 0.2560) and *RO: O altă problemă importantă cu care trupele Antantei au fost obligate să se confrunte a fost malaria. (Another important problem that the Triple Entente troops had to face was malaria.)* - EN: *Another important problem that Antarctic troops had to face was malaria.* (expected: 0.2813, predicted: -0.9050). In the opinion of the authors of this paper, it is debatable whether the expected scores for these two pairs should be so different. Both of them have obvious problems and cannot be clearly understood without reading the source. For this reason, we would expect that both of them have low scores. Instances like this also occur in the training data. As a result of this, it may be that *TransQuest* learns contradictory information, which in turn leads to errors at the testing stage.

A large number of problems are caused by incomplete source sentences or input sentences with noise. For example the pair *RO: thumbright250pxDrapelul cu fâșiile în poziție verticală (The flag with strips in upright position) - EN: ghtghtness 250pxDrapel with strips in upright position* has an expected score of 0.0595, but

our method predicts -0.9786. Given that only *ghtghtness 250pxDrapel* is wrong in the translation, the predicted score is far too low. In an attempt to see how much this noise influences the result, we run the system with the pair *RO: Drapelul cu fâșiile în poziție verticală - EN: Drapel with strips in upright position*. The prediction is 0.42132, which is more in line with our expectations given that one of the words is not translated.

Similar to Ro-En, in Si-En the majority of problems seem to be caused by the presence of named entities in the source sentences. For an example in the English translation: *But the disguised Shiv will help them securely establish the statue.* (expected: 1.3618, predicted: -0.008), the correct English translation would be *But the disguised Shividru will help them securely establish the statue.*. Only the named entity *Shividru* is translated incorrectly, therefore the annotators have annotated the translation with a high quality. However TransQuest fails to identify that. Similar scenarios can be found in English translations *Kamala Devi Chattopadhyay spoke at this meeting, Dr. Ann.* (expected:1.3177, predicted:-0.2999) and *The Warrior Falls are stone's, halting, heraldry and stonework rather than cottages. The cathedral manor is navigable places* (expected:0.1677, predicted:-0.7587). It is clear that the presence of the named entities seem to confuse the algorithm we used, hence it needs to handle named entities in a proper way.

5 Conclusion

In this paper we evaluated different settings of *TransQuest* in sentence-level direct quality assessment. We showed that ensemble results with XLM-R-base and XLM-R-large with data augmentation techniques can improve the performance of TransQuest framework.

The official results of the competition show that *TransQuest* won the first place in all the language pairs in Sentence-Level Direct Assessment task. *TransQuest* is the sole winner in En-Zh, Ne-En and Ru-En language pairs and the multilingual track. For the other language pairs (En-De, Ro-En, Et-En and Si-En) it shares the first place with another system, whose results are not statistically different from ours. The full results of the shared task can be seen in Specia et al. (2020).

In the future, we plan to experiment more with the data augmentation settings. We are interested in augmenting the training file with semantically similar sentences to the test set rather than augmenting with random sentence pairs as we did in this paper. As shown in the error analysis in Section 4.4 the future releases of the framework need to handle named entities properly. We also hope to implement *TransQuest* in document level quality estimation too.

Abstract

This paper presents our work in the WMT 2020 Word and Sentence-Level Post-editing Effort Quality Estimation (QE) Shared Task. Our system follows standard Predictor-Estimator architecture, with a pre-trained Transformer as the Predictor, and specific classifiers and regressors as Estimators. We integrate Bottleneck Adapter Layers in the Predictor to improve the transfer learning efficiency and prevent from over-fitting. At the same time, we jointly train the word- and sentence-level tasks with a unified model with multitask learning. Pseudo-PE assisted QE (PEAQE) is proposed, resulting in significant improvements on the performance. Our submissions achieve competitive result in word/sentence-level sub-tasks for both of En-De/Zh language pairs.

1 Introduction

Quality Estimation (QE) assesses the translation quality of machine translation (MT) system output when ground truth reference is not available (Specia et al., 2013, 2018). For the word-level QE task, participants are required to tag tokens and gaps of the translation output from an unknown MT system with OK and BAD, as well as tokens in the source with the same tags. The result is measured by Matthews Correlation Coefficient (MCC). For the sentence-level task, participants are required to predict the Human Translation Error Rate (HTER) scores of the machine translation outputs and the result is evaluated in terms of the Pearson's correlation coefficient.

Our team participates in some of the sub-tasks in two language pairs (En-De and En-Zh) (Specia et al., 2020). With regard to the En-De track, at word-level, our model achieves the MCC score of 0.5828 on the target side, and 0.5234 on the source side; at sentence-level, our model ranks the first place with a Pearson R score of 0.7583. With regard to the En-Zh track, we only submit the target side of word-level sub-task, and achieves a MCC score of 0.5872.

Our system is implemented with fairseq (Ott et al., 2019) (for En-De track) and THUMT (Zhang et al., 2017) (for En-Zh track). We extend the original Transformer (Vaswani et al., 2017) model to fit the QE task, and leverage transfer learning to fine-tune the model with the task specific dataset (Dai and Le, 2015; Howard and Ruder, 2018; Radford et al., 2018). The contributions of our work are as follows:

- We follow the Predictor-Estimator (Kim and Lee, 2016; Kim et al., 2017; Wang et al., 2018; Li et al., 2018; Kepler et al., 2019) architecture and build a unified QE model based on the standard Transformer MT model.
- Bottleneck Adapter Layers (Houlsby et al., 2019; Yang et al., 2020) are integrated into the model for efficient transfer learning.
- We propose the Pseudo-PE assisted QE (PEAQE) method which effectively improve the performance.

The architecture of our model is shown in Figure 1.

2 Task Description

A more detailed description of the word- and sentence-level QE tasks is given in this section.

2.1 Word-Level

Word-level QE estimates the translation quality by producing a sequence of tags for both source and target. For target sentences, both tokens and gaps are required to be tagged with OK or BAD, while for source sentences, only tokens are tagged

Proceedings of the 5th Conference on Machine Translation (WMT), pages 1056–1061

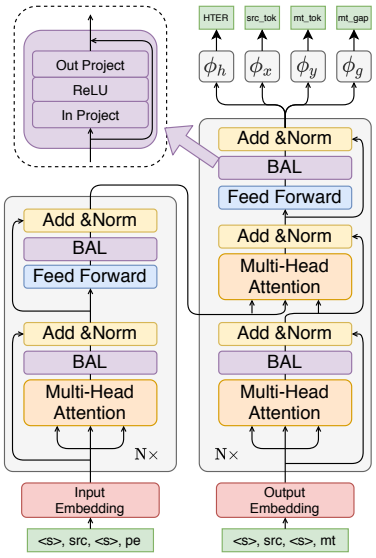

Figure 1: This figure shows the architecture of our model, where SRC and Pseudo-PE are concatenated as the encoder input, a copy of SRC and MT are concatenated as the decoder input. The output feature are passed through four linear layers to make prediction for four tasks.

with OK or BAD. This is usually modelled as a sequential labelling problem. The tag of token indicates whether the word is correctly translated or not, while the tag of gap indicates whether one or more words are missing here. The number of total tags for each MT sentence is $2N + 1$, where N is the number of tokens in the sentence.

The evaluation metrics of the word-level task is the Matthews Correlation Coefficient (MCC), an appropriate measurement for unbalanced labels. MCC is defined as follows:

$$S = \frac{TP + FN}{N}$$
$$P = \frac{TP + FP}{N}$$
$$MCC = \frac{\frac{TP}{N} - SP}{\sqrt{SP(1-S)(1-P)}}, \quad (1)$$

where TP, TN, FP and FN represent for true positives, true negatives, false positives and false positives respectively; and N is the number of instance (Fonseca et al., 2019).

2.2 Sentence-Level

The sentence-level QE predicts the Human Translation Error Rate (HTER) (Specia et al., 2018) of given translation outputs. HTER is an edit-distance measure, calculating the ratio between the number of edits (insertions/deletions/replacements) required and the reference translation length, namely HTER = (Insertions + Delations + Replacement) / Reference Words. In the QE task, where references are not available, HTER is roughly an estimation. As HTER is a real value ranging from 0 to 1, it can be modeled as a regression task. The evaluation metrics of the sentence-level task is the Pearson correlation coefficient.

Attributes	En-De	En-Zh
# Instance	7,000	7,000
# SRC Token	11,4980	115,585
# MT Token	112,342	120,015
% MT Token BAD	28.15	54.33
% MT Gap BAD	4.60	8.04
% SRC Token BAD	26.95	53.60
BLEU (MT, PE)	49.40	30.40
μ(HTER)	0.3181	0.6280
σ(HTER)	0.2017	0.2040

Table 1: The statistics of the training set for both language pairs.

3 Dataset

The dataset contains 7,000 sentences for the training set, 1,000 for the dev and 1,000 for the test. Except from tags and HTER scores (labels), the dataset also provides post-edit (PE) text, as the reference for generating QE labels. Note that this data is also used in the Automatic Post Editing task in WMT 2020. Detailed statistics of the dataset is listed in Table 1, with some metrics of the source (SRC) and translation (MT). The proportion of BAD tags agains OK tags is imbalanced, especially for Gap tags.

Apart from the brief descriptive statistics listed in the table, our in-depth investigation on the provided dataset unveils some interesting findings:

- Different from the dataset in WMT 2019 QE task (Fonseca et al., 2019), which is sampled from IT domain, the dataset this year is collected from Wikipedia. Therefore, mixing data from previous years may not help to improve this year's performance.

- The BLEU score (Papineni et al., 2002) for 2020 dataset is significantly lower than that of 2019, indicating much more operations are required to edit the translation outputs into the references. As a result, the distribution

of labels for 2020 dataset is changed as well when comparing with that of last year.

Unlike a standard translation task, where various data augmentation techniques, such as back-translation (Sennrich et al., 2016), are available, QE task can hardly be improved with data augmentation, as it requires unbiased and high-quality PEs to generate tags and HTER scores. Meanwhile, the change of dataset domain makes it impossible to enlarge the dataset by incorporating the dataset of last year. Facing this challenging task, we propose the PEAQE method, which will be further explained in details in the following section.

4 Model

4.1 Unified QE Model

Our model follows the Predictor-Estimator (Kim et al., 2017; Kepler et al., 2019) architecture. The Predictor is considered as a feature extractor, which can be a pre-trained language model (LM) or a translation model. In our implementation, we use the standard Transformer without the causal mask as the Predictor, which is pre-trained with dataset in news translation task of WMT 2019 En-De and WMT 2020 En-Zh. The Estimator can be task specific classifiers which map the extracted features into the target space, and can be modelled by several fully connected layers. We use a unified QE model to solve both word- and sentence-level tasks by building three classifiers and a regressor to make prediction on SRC tag, MT token tag, MT gap tag and HTER score, respectively.

We define the encoder and decoder of the Transformer as functions f and g; SRC and MT text as X and Y; tags of SRC, MT token and MT gap as V_x, V_y, V_g; and HTER score as V_h. The representation $\mathbf{H}_X$ and $\mathbf{H}_Y$ are obtained by passing the X and Y into the encoder and decoder respectively:

$$\mathbf{H}_X = f(X) \tag{2}$$

$$\mathbf{H}_Y = g(Y, \mathbf{H}_X). \tag{3}$$

For a translation model, we usually append and prepend the special token $\langle s \rangle$ to the SRC and TGT text. Here we follow the same rule and thereby the lengths of SRC and MT embeddings are $M+1$ and $N+1$ respectively. Meanwhile, we append and prepend a special label $\langle pad \rangle$ to the original label sequence during training, but loss of the padded label is not computed. All predictions are obtained by performing specific transformations $\phi_\cdot$ on the hidden stats:

$$\hat{V}_x = \phi_x(\mathbf{H}_X) \tag{4}$$

$$\hat{V}_y = \phi_y(\mathbf{H}_Y) \tag{5}$$

$$\hat{V}_g = \phi_g(\mathbf{H}_Y) \tag{6}$$

$$\hat{V}_h = \phi_h(h_{Y,0}). \tag{7}$$

Note that the regressor ϕ_h only takes the embedding of the MT's first token to make predictions, similar to the usage of [CLS] in BERT (Devlin et al., 2018).

For all classification tasks, we use weighted cross entropy as the loss function, and the weight is calculated as follows: $w_i = \frac{\sum |C_i|}{|C_i|}$, which is the inverse of the proportion of the instance with class C_i. We use weighted cross entropy because labels are highly imbalanced, and the loss should be manipulated with the weight. For sentence-level QE, we use mean squared error (MSE) as the loss function, which is quite intuitive.

The model is trained under the multi-task learning framework by summing up the loss of all subtasks with specific weights:

$$\begin{aligned}\mathcal{L} =& \lambda_h \sqrt{(\hat{V}_h - V_h)^2} \\ &- \sum_{\tau \in \{x,y,g\}} \lambda_\tau \log P(V_\tau | X, Y),\end{aligned} \tag{8}$$

where $\{x, y, g\}$ represents for classification tasks and h represents for regression task, and λ is the weight of loss for a specific task. Although the multi-task setting could improve the overall performance, the evaluation is performed separately, it means we can train models that are optimized for the specific task, which can be achieved by giving larger weight to the loss of that task.

4.2 Bottleneck Adapter Layer

As mentioned in the previous section, the provided training set is relatively small, make the model to be easily over-fitted if all weights are updated. Therefore, we decide to integrate the Bottleneck Adapter Layers (BAL) (Houlsby et al., 2019) while keeping parameters of original Transformer fixed (Yang et al., 2020).

BAL can be easily implemented with two fully-connected layers with a non-linear activation, and is embedded into the Transformer with residual connections after the self-attention layer and the FFN layer, respectively.

In the experiment, we find that the bottle with a "thick" neck ("like FFN layers in the Transformer with higher dimension in the middle part") could further improve the performance without seriously sacrificing training efficiency. More specifically, we tested three neck sizes, i.e. thin, same and thick. The thin and same neck basically reaches 97%-99% of performance compared with training the full Transformer without using BAL, which yields the same result with (Houlsby et al., 2019). By increasing the parameter size of BALs, we find that the performance also increases linearly, finally reaching the pick of 104% of the baseline performance with the neck to have 2 $\times$ hidden size.

4.3 Pseudo-PE Assisted QE

QE tags can be generated with post-edits (PEs) or reference (REF) of MT. In this dataset, PE is provided, and QE tags are generated accordingly, if PE can be directly used to assist the model learning QE tags, the training efficiency will be dramatically increased. Inspired by the Pseudo-PE technique proposed in the (Kepler et al., 2019), we hope to fully leverage PE, for example, integrating them as part of the network input. However, for the test set, where PEs are not available, we must find an alternative approach. So, we made following assumption:

$$\delta(\text{MT}, \text{REF}) \approx \delta(\text{MT}, \text{PE}) + \delta(\text{PE}, \text{REF}), \quad (9)$$

where δ is any distance measurement function. In the equation, PE is regarded as an intermediate node between MT and REF. Under such assumption, if we could find any translation that is better than MT, although not as good as PE, the translation can also be used as a substitute of PE, denoted as PE'. we call this method as Pseudo-PE assisted QE (PEAQE). Finding PE' is relatively easy when we could access unconstrained resources. Using an APE system or a robust online translation system to produce better translation outputs are two feasible approaches. After comparing the BLEU scores of the training set between many online translation services and an APE system trained by us, we decide to use Google Translate outputs as the Pseudo-PE. The BLEU score for official MTs and Google MTs in the dev set are 50.9/ 67.8 for En-De, and 22.62/41.77 for En-Zh, indicating that Google MT outputs, with a high quality, could be used as Pseudo-PEs in the testing phase.

To leverage PEs, we simply concatenate them with the SRCs and encoded them via an encoder. We find that using the features of SRC text from the encoder could not produce acceptable predictions. Therefore, we decide to concatenate SRCs with MTs again on the decoder side, and use the decoder to extract features for both of them. More formally:

$$\mathbf{H}_{[X;Z]} = f([X; Z]) \quad (10)$$

$$\mathbf{H}_{[X;Y]} = g([X; Y], \mathbf{H}_{[X;Z]}), \quad (11)$$

where Z represents for official PEs (training) or Pseudo-PEs (testing). Finally, the hidden state $\mathbf{H}_{[X;Y]}$ is sliced with the max length of X, and recover back to $\mathbf{H}_X$ and $\mathbf{H}_Y$, which are used as in the original model. Official PE and Pseudo-PE can be used respectively during training and testing to assist the model to make better prediction.

5 Experiment

Our experiments of all sub-tasks for En-De and part of sub-tasks for En-Zh trak are performed on the WMT 2020 dataset. The model without Pseudo-PE assistance is considered as the baseline.

5.1 Experimental Settings

Our models are implemented with fairseq (Ott et al., 2019) and THUMT (Zhang et al., 2017). The fairseq version mainly deals with En-De tasks thanks to the pre-trained models trained in WMT 2019 news translation task. The En-Zh pre-trained model is implemented with THUMT and is trained in WMT 2020 news translation task by our team. For the En-De model, input and output embeddings are shared, therefore SRC and TGT text can be conveniently concatenated. For the En-Zh model, vocabulary is not shared, when creating the input sequence, we firstly pass tokens of English (SRC) and Chinese (MT and PE) with specific word embedding layer respectively, and than, concatenate the hidden states of them accordingly. The number of parameters of the En-De and En-Zh models are 270M and 353M, respectively. The batch size used for training is 32. We use Adam (Kingma and Ba, 2015) to optimize parameters with learning rate of 1e-4 without any scheduler. Note that when dealing with labels of sub-tokens, for each token, we only assign the first sub-token with the label and subsequent sub-tokens are assigned with the dummy pad labels, which keeps the distribution of labels unchanged. Our QE models are trained on a Nvidia Tesla V100 GPU, and converge within 5 epochs.

Lang	Model	MCC-MT	MCC-SRC	Pearson-R
En-De (Dev)	Baseline	44.50	32.46	55.26
	+ PEAQE	60.05	45.31	71.69
	+ Ensemble (14)	64.70	51.17	73.33
En-De (Test)	+ Ensemble (14)	58.28	52.34	75.83
En-Zh (Dev)	Baseline	43.06	-	-
	+ PEAQE	57.90	-	-
	+ Ensemble (5)	59.28	-	-
En-Zh (Test)	+ Ensemble (5)	58.72	-	-

Table 2: The experimental results of our model, where the baseline model is introduced in section 4.1. The evaluation results of the test set are from the official leader-board.

5.2 Experimental Results

Table 2 shows the experimental results on the dev and test sets. The performance of the baseline model is relatively poor. By leveraging PEAQE, the model achieves much better performance, demonstrating that integrating PE directly into the QE model could effectively assist the prediction. With PEs, the model can receive stronger supervision signal and is actually learning the procedure done by the tagging script, making the entire learning process easier. However, we clearly understand that the performance of PEAQE strongly depends on the quality of Pesudo-PEs, which becomes another problem that should be solved in the future.

Here is another interesting finding during our experiment. Initially, we also performed experiments with mBERT (Devlin et al., 2018) and XLM (Conneau and Lample, 2019) but not producing desirable results. The reason might be size of the dataset. We find that performing transfer learning with pre-trained NMT model on the limited size QE dataset is more effective than other pre-trained multilingual LMs. We consider that NMT models are naturally fit for MT related tasks because of the learned prior between bilingual text, which might not be captured by multilingual LMs where text in different languages are trained independently.

6 Conclusion

We present our works for WMT 2020 QE shared task. The experimental results demonstrate that performing transfer learning with a pre-trained NMT model on the QE task is effective. Compared to only using SRC and MT text, we propose PEAQE which could significantly improve the performance of the model. But generating reliable Pseudo-PEs that are compatible with QE tasks remains a problem that would be investigated in our future works.

Abstract

This paper presents Tencent's submission to the WMT20 Quality Estimation (QE) Shared Task: Sentence-Level Post-editing Effort for English-Chinese in Task 2. Our system ensembles two architectures, XLM-based and Transformer-based Predictor-Estimator models. For the XLM-based Predictor-Estimator architecture, the predictor produces two types of contextualized token representations, i.e., masked XLM and non-masked XLM; the LSTM-estimator and Transformer-estimator employ two effective strategies, top-K and multi-head attention, to enhance the sentence feature representation. For Transformer-based Predictor-Estimator architecture, we improve a top-performing model by conducting three modifications: using multi-decoding in machine translation module, creating a new model by replacing the transformer-based predictor with XLM-based predictor, and finally integrating two models by a weighted average. Our submission achieves a Pearson correlation of 0.664, ranking first (tied) on English-Chinese (Specia et al., 2020).

1 Introduction

The development of Machine Translation (MT) requires efficient quality evaluation of the outputs. The widely used MT metric BLEU (Papineni et al., 2002) satisfies this demand. However, BLEU requires human reference translations which costs labor and time to generate. Quality Estimation (QE) is an alternative to evaluate the quality of MT outputs with no access to reference translations (Fonseca et al., 2019; Yang et al., 2019).

We participate in the sentence-level task in Task 2 of the WMT20 QE Shared Task for English–Chinese (Specia et al., 2020). The sentence-level task aims to predict the Human-targeted Translation Edit Rate (HTER) (Snover et al., 2006) of the MT output, which reflects the minimal amount of edits that is needed to post-edit the MT output to an acceptable one, thus denotes the overall quality of the MT output.

The classical baseline model QuEst++ (Specia et al., 2015) constructed rule-based features and employed machine learning algorithm to predict HTER scores. Recent neural networks applied the newly-emerged predictor-estimator architecture to QE tasks. Kim et al. (2017) proposed the first predictor-estimator model to extract feature vectors by incorporating large parallel data into a bilingual RNN model, which is subsequently fed into another bidirectional RNN model to predict QE scores. Later on, Fan et al. (2019) replaced the RNN-based predictor by a bidirectional Transformer and added 4-dimensional mis-matching features; Wang et al. (2019) used a Transformer-DLCL based predictor; and Kepler et al. (2019a) introduced BERT and XLM pretrained predictors into their system. Besides the improvements on model architectures, choosing the top-performing models using ensemble techniques further improves the QE performance. For example, the submission using ensemble techniques achieved the best result in the sentence-level QE sub-task in both WMT19 (Fonseca et al., 2019) and CCMT19 (Yang et al., 2019).

We submit a predictor-estimator based QE system, which extends the open-source OpenKiwi framework[1] (Kepler et al., 2019b) to take advantage of recently proposed pre-trained models by transfer learning technique. Our contributions are as follow:

- We propose XLM-based Predictor-Estimator architecture, which introduces the cross-lingual language model (XLM) (Lample and Conneau, 2019) to QE task via transfer learning technique. Instead of directly using target

Proceedings of the 5th Conference on Machine Translation (WMT), pages 1062–1067
Online, November 19–20, 2020.

word representations produced by XLM as the predictor output, we propose non-masked XLM representation and masked XLM representation, and adopt further computation to enhance the feature extraction ability.

- We implement LSTM-based estimator and Transformer-based estimator, with two novel strategies to enhance the sentence feature representation, i.e. top-K strategy and multi-head attention strategy.

- We reform Transformer-based Predictor-Estimator (Fan et al., 2019) by using multi-decoding during the machine translation module. Besides, we create a new model by replacing the transformer-based predictor with XLM-based predictor, and then integrate the two models by weighted average.

- We ensemble several single-models by regression algorithms to produce a single sentence-level prediction, which outperforms the commonly-used arithmetic average.

We next describe the models, experiments and results in detail.

2 Models

Our models employ predictor-estimator architecture and OpenKiwi framework. Overall, we implement two predictor-estimator architectures, namely XLM-based Predictor-Estimator and Transformer-based Predictor-Estimator, and ensemble multiple systems to boost performance.

2.1 XLM-based Predictor-Estimator

XLM achieved state-of-the-art performances on several NLP tasks (Lample and Conneau, 2019). We extend XLM by transferring the language model to QE task and proposing a novel XLM-based Predictor-Estimator model.

2.1.1 Predictor

For predictor, we fine-tune XLM with both Masked Language Modeling (MLM) task and Translation Language Modeling (TLM) task using large-scale parallel data following the XLM instructions.[2]

[2]https://github.com/facebookresearch/XLM

XLM representations Instead of using target word representation produced by the fine-tuned XLM as the predictor output as in Kepler et al. (2019a), we propose non-masked XLM representation and masked XLM representation, and adopt further computation to enhance the feature extraction ability. For non-masked XLM, all words are fed into the XLM to predict each word's representation, letting the word itself help to predict its representation. For masked XLM, one target word is masked one time so that the prediction of the masked word leverages information only from the surrounding words and the source context, without any prior information from itself.

Let the length of the target sentence be N, the masking process is repeated N times and then all target word representations are generated. We consider two aspects that influence word representation: the weight of each dimension in the word representation and the language embeddings. Formula (1) describes the final word representation, which is then fed into the estimator as input features to predict HTER scores.

$$Rep_i = R_i \cdot (W_i + Emb_{lang}) \quad (1)$$

In formula (1), i refers to the i-th word in the target sentence and R_i refers to the original representation of the i-th word. W_i denotes the weights of each dimension for the i-th word and Emb_{lang} denotes the language embedding of the target sentence. Rep_i is the final representation of the i-th word.

2.1.2 Estimator

Estimator takes features produced by predictor as the input to predict sentence-level scores of MT outputs. We implement a multi-layer LSTM-estimator and a Transformer-estimator, both of which adopt state-of-the-art strategies to optimize the sentence features.

The last state or the the mean pooling of hidden states are usually taken as the sentence representation. However, they both have weaknesses: the last state losses certain information of the whole sentence due to the information decay problem, while the mean pooling distributes the same weights to all hidden Actually, the contribution of each word to the sentence features varies, which inspires us to take the concept of weight into consideration. We propose two strategies, top-K strategy and multi-head attention strategy to optimize weights from

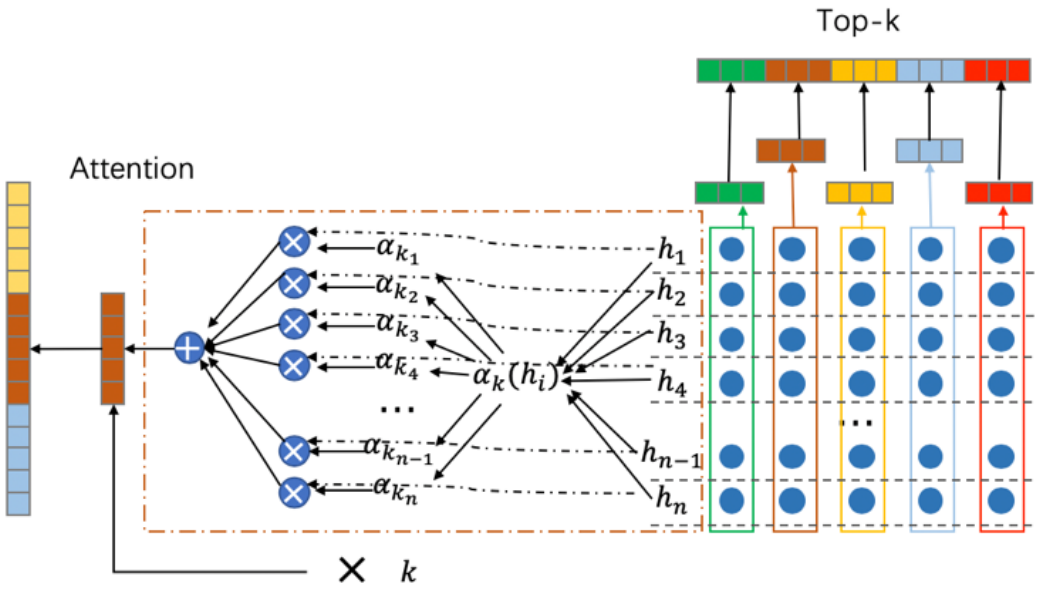

Figure 1: Top-K strategy and Multi-head attention strategy illustration.

two different perspectives, as shown in Figure 1.

Top-K Strategy The hidden state of each word is a vector, and each element of the vector represents one feature dimension. The top-K strategy forms sentence features by concatenating top K elements of each of N feature dimension, creating a vector of size K * N.

Multi-head Attention Strategy Different from Top-K strategy, multi-head attention strategy considers the impact of each word on the sentence features via attention mechanism. For each head, we obtain a vector which is a weighted sum of all the word features. By repeating K times, the final sentence feature is a vector with size K * N. We demonstrate the computation process as in Formula (2) and (3),

$$a_{k_i} = softmax(h_i * W_k), \tag{2}$$

$$f_{sent} = [\sum_i a_{1_i} * h_i, \ldots, \sum_i a_{k_i} * h_i] \tag{3}$$

where a_{k_i} is attention results of each word (h_i), and f_{sent} is the final sentence feature representation.

2.2 Transformer-based Predictor-Estimator

Transformer-based Predictor-Estimator architecture has been proved effective by Fan et al. (2019). Our predictor follows their bidirectional transformer, which contains three modules: self-attention for the source sentence, forward and backward self-attention encoders for the target sentence, and the re-constructor for the target sentence. We include semantic features extracted by bidirectional transformer and human-crafted mismatching features in the model. Our Transformer-based model has three main improvements:

- For transformer-based predictor, we use multi-decoding during the machine translation module.
- We create a XLM-based predictor, which simply replace the predictor part by XLM.
- We take the weighted average of the two models as the final sentence-level prediction as shown in Formula (4). We set α to be 0.8 since the transformer-based predictor contributes more than the XLM-based predictor.

$$Score = \alpha * Score_{Transformer} + (1 - \alpha) * Score_{XLM} \tag{4}$$

2.3 Ensemble

To boost performance, we ensemble several systems to produce a single sentence score prediction. Model stacking (Wolpert, 1992; Breiman, 1996) is an efficient ensemble method in which the predictions, generated by using various single systems, are used as inputs in a second-layer regression algorithm. To avoid over-fitting, we use k-fold cross validation with k = 5 (Martins et al., 2017).

We implement and compare several regression algothrims, i.e., Powell's method (Powell, 1964), Quantile Regression, Support Vector Regression (SVR), and Logistic Regression (LR) to optimize the task on Pearson correlation.

3 Experiments and Results

We conducted three sets of experiments on the WMT20 QE English-Chinese Sentence-level Task in Task 2.

3.1 Dataset

The dataset consists of parallel data between English and Chinese, as well as QE triplets with source texts, target translations and HTER scores. The parallel data is used to train the predictor to produce contextualized features. Specifically, we sampled 45M English-Chinese parallel sentences to train the XLM-based Predictor. For Transformer-based Predictor, we combined the subset of 8.9M parallel sentences in CCMT20 with a set of 15K pseudo data constructed by augmenting the number of entities within the sentences.

3.2 Experiments

3.2.1 Experiments with XLM-based Predictor-Estimator

We experiment with non-masked ($non\text{-}masked$) and masked XLM ($masked$) predictors. We also try to concatenate feature vectors produced by two predictors ($Both$) as the input of the next estimator procedure. For every predictor, we conduct experiments with LSTM-estimator ($LSTM$) and Transformer-estimator (TF), each of which adopts multi-head attention strategy ($attn$) or top-K strategies ($topK$) to improve the sentence representation.

The results in Table 1 show that our QE systems with XLM predictor achieve strong correlation with HTER scores in general. The model with both predictors, LSTM-estimator and multi-head attention strategy (*Both_LSTM_attn*) ranks top with a Pearson score of .6348.

Model	Pearson
Both_LSTM_attn	**.6348**
Both_LSTM_topK	.6244
Both_TF_attn	.6218
Both_TF_topK	.6276
masked_LSTM_attn	.6232
masked_LSTM_topK	6156
masked_TF_attn	.6143
masked_TF_topK	.6260
non-masked_LSTM_attn	.6142
non-masked_LSTM_topK	.6216
non-masked_TF_attn	.6234
non-masked_TF_topK	.6268

Table 1: Pearson correlations of single QE systems with XLM-based Predictor-Estimator on WMT20 English-Chinese development set for sentence-level task.

3.2.2 Experiments with Transformer-based Predictor-Estimator

We extend Transformer-based predictor-estimator (Fan et al., 2019) with the following modifications: we use multi-decoding during Transformer-based predictor, replace Transformer-based predictor with XLM-based predictor to form a new model, and then integrate the two models into one by weighted average with more weights on the Transformer-based predictor.

Table 2 presents the key configurations and results in Transformer-based experiments. Among the four models, Models 1–3 integrate XLM-based estimators into the architecture and achieve the highest Pearson correlations of .646–.647. These integrated models vary in two configurations: whether or not the XLM-estimator has been fine-tuned and whether or not to include source information. We conclude that XLM-based model helps improve Transformer-based Predictor-Estimator performance.

3.2.3 Experiments with ensemble methods

We conduct multiple single QE systems through different model architectures or the same architecture with different parameters. Specifically, we include predictions from 24 XLM-based and 5 Transformer-based Predictor-Estimator systems, and stack them using 4 regressors: Powell's, Quan-

	Transformer	XLM Estimator			Pearson
		Included?	Finetuning?	Input	
Model 1	✔	✔	✔	source & target	**.646**
Model 2	✔	✔	✔	target only	**.647**
Model 3	✔	✔	✘	target only	**.647**
Model 4	✔	✘	N/A	N/A	.633

Table 2: Pearson correlations of single QE systems with Transformer-based Predictor-Estimator on WMT20 English-Chinese development set for sentence-level task.

tile Regression, SVR and LR.

Results in Table 3 prove the effectiveness of ensemble techniques, when compared to results shown in Tables 1 and 2. We also conclude that regression algorithms outperform simple averaging ("Average" in Table 3), and among them, Logistic Regression achieves the best Pearson score of .6785.

Ensemble methods	**Pearson**
Average	.6521
Powell's	.6515
Quantile Regression	.6699
Support Vector Regression	.6735
Logistic Regression	**.6785**

Table 3: Pearson correlations of ensemble QE systems on WMT20 English-Chinese development set for sentence-level task.

4 Conclusion

We describe Tencent's submission to the WMT20 Quality Estimation sentence-level task in task 2. Our systems are based on predictor-estimator architecture and built upon OpenKiwi framework. We implement two predictor-estimator architectures, XLM-based Predictor-Estimator and Transformer-based Predictor-Estimator. For XLM-based Predictor-Estimator, we produces two kinds of contextual token representation, masked and non-masked representations. Both LSTM-estimator and Transformer-estimator are conducted to predict the MT output scores by using the features produced from the predictors. Top-K strategy and multi-head attention strategy are employed to enhance the sentence feature representation. For Transformer-based Predictor-Estimator, we integrate one model based on XLM-based predictor to enhance the overall performance. Stacking ensemble is also proved to be more effective than simple averaging integration.

Abstract

This paper describes our submission of the WMT 2020 Shared Task on Sentence Level Direct Assessment, Quality Estimation (QE). In this study, we empirically reveal the *mismatching issue* when directly adopting BERTScore (Zhang et al., 2020) to QE. Specifically, there exist lots of mismatching errors between source sentence and translated candidate sentence with token pairwise similarity. In response to this issue, we propose to expose explicit cross lingual patterns, *e.g.* word alignments and generation score, to our proposed zero-shot models. Experiments show that our proposed QE model with explicit cross-lingual patterns could alleviate the mismatching issue, thereby improving the performance. Encouragingly, our zero-shot QE method could achieve comparable performance with supervised QE method, and even outperforms the supervised counterpart on 2 out of 6 directions. We expect our work could shed light on the zero-shot QE model improvement.

1 Introduction

Translation quality estimation (QE) (Blatz et al., 2004; Specia et al., 2018, 2020) aims to predict the quality of translation hypothesis without golden-standard human references, setting it apart from reference-based translation metrics. Existing reference-based evaluation metrics, e.g. BLEU (Papineni et al., 2002), METEOR (Banerjee and Lavie, 2005), NIST (Doddington, 2002), ROUGE (Lin, 2004), TER (Snover et al., 2006), are commonly used in language generation tasks including translation, summarization, and captioning but all heavily rely on the quality of given references.

Recently, (Edunov et al., 2020) show that reference-based automatic evaluation metrics, e.g., BLEU, are not always reliable because the human translated references are translationese (Koppel and Ordan, 2011; Graham et al., 2019). Thus, an automatic method with no access to any references, i.e., QE, is highly appreciated.

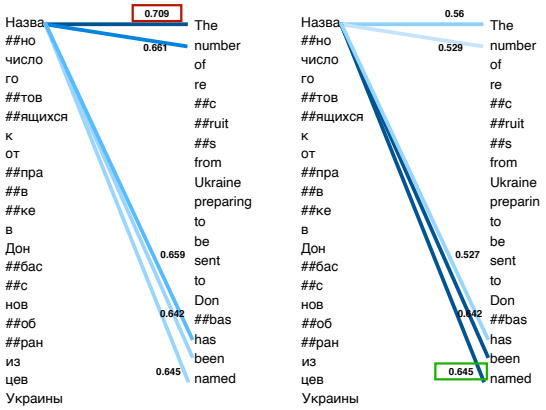

Figure 1: Example of mismatching error, Russian→English. On the left, token "Назва" is mismatched to "The" with the maximal probability (within the red rectangle) only. On the right, guided by our proposed cross-lingual patterns, "Назва" is correctly matched to the token "named" with the maximal probability (within the green rectangle.)

In this paper, we mainly focus on sentence level QE metrics, where existing studies categorize it into two classes: 1) supervised QE with human assessment as supervision signal: a feature extractor stacked with an estimator (Yankovskaya et al., 2019; Wang et al., 2016b; Fan et al., 2019); 2) unsupervised QE without human assessment, which normally based on the pre-trained word embeddings, for example, YISI (Lo, 2019) and BERTScore (Zhang et al., 2020). Our work follows the latter, where we adopt BERTScore (Zhang et al., 2020) without extra fine-tuning. In particular, we implement our approach upon the pre-trained multilingual BERT (Devlin et al., 2019) and XLM (Conneau and Lample, 2019).

We first empirically reveal the *mismatching issue* when directly adopting BERTScore (Zhang

Proceedings of the 5th Conference on Machine Translation (WMT), pages 1068–1074

et al., 2020) to QE task. Specifically, there exist lots of mismatching errors between source tokens and translated candidate tokens when performing greedy matching with pairwise similarity. Figure 1 shows an example of the mismatching error, where the Russian token "Назва" is mismatched to the English token "The" due to lacking of proper guidance.

To alleviate this issue, we design two explicit cross-lingual patterns to augment the BERTScore as a QE metric:

- CROSS-LINGUAL ALIGNMENT MASKING: we design an alignment masking strategy to provide the pairwise similarity matrix with extra guidance. The alignment is derived from GIZA++ (Och and Ney, 2003).
- CROSS-LINGUAL GENERATION SCORE: we obtain the perplexity, dubbed *ppl*, of each target side token by force decoding with a pre-trained cross-lingual model, e.g. multilingual BERT and XLM. This generation score is weighted added on the similarity score.

2 Methods

2.1 BERTScore as Backbone

A pre-trained multilingual model generates contextual embeddings of both source sentence and translated candidate sentence, such that this pair of sentences in different language can be mapped to the same continuous feature space. Given a source sentence $x = \langle x_1, \ldots, x_k \rangle$, the model generates a sequence of vectors $\langle \mathbf{x_1}, \ldots, \mathbf{x_k} \rangle$ while the candidate $\hat{y} = \langle \hat{y}_1, \ldots, \hat{y}_l \rangle$ is mapped to $\langle \hat{\mathbf{y}}_\mathbf{1}, \ldots, \hat{\mathbf{y}}_\mathbf{l} \rangle$. Different from the reference-based BERTScore, where they compute the pairwise similarity between reference sentence and translated candidate sentence, we calculate the pairwise similarity between the source and translated candidate with dot-production, i.e., $\mathbf{x_i}^\top \hat{\mathbf{y}}_\mathbf{j}$. We adopt greedy matching to force each source token to be matched to the most similar target token in the translated candidate sentence. The QE function based on BERTScore backbone therefore can be formulated as:

$$
\begin{aligned}
R_{\text{BERT}} &= \frac{1}{|x|} \sum_{x_i \in x} \max_{\hat{y}_j \in \hat{y}} \mathbf{x_i}^\top \hat{\mathbf{y}}_\mathbf{j}, \\
P_{\text{BERT}} &= \frac{1}{|\hat{y}|} \sum_{\hat{y}_j \in \hat{y}} \max_{x_i \in x} \mathbf{x_i}^\top \hat{\mathbf{y}}_\mathbf{j}, \\
F_{\text{BERT}} &= 2 \frac{P_{\text{BERT}} \cdot R_{\text{BERT}}}{P_{\text{BERT}} + R_{\text{BERT}}}.
\end{aligned}
\tag{1}
$$

where R_{BERT}, P_{BERT} and F_{BERT} are inherited from Zhang et al. (2020), representing Recall rate, Precision rate and F-score, respectively.

2.2 Alignment Masking Strategy

With aforementioned QE function, we can follow Zhang et al. (2020) to obtain the distance between the source sentence and translated candidate sentence via directly adding up the maximum similarity score of each token pair. However, because there exist lots of mismatching errors (as shown in Figure 1), above sentence-level similarity calculation may be sub-optimal. Moreover, Zhang et al. (2020)'s calculation is suitable for monolingual scenario, which may be insensitive for cross-lingual computation. Thus, we propose to augment our QE metric with more cross-lingual signals.

Inspired by Ding et al. (2020), where they show it's possible to augment cross-lingual modeling by leveraging cross-lingual explicit knowledge. we therefore employ word alignment knowledge from external models, e.g., GIZA++[1], as additional information.

Alignment masking Both BERT (Devlin et al., 2019) and XLM (Conneau and Lample, 2019) utilize BPE tokenization (Sennrich et al., 2016). It should be noted that in this paper, by word alignment we mean alignment of BPE tokenized word and subword units. Given a tokenized source sentence x and candidate sentence $\hat{y}$, alignment (Och and Ney, 2003) is defined as a subset of the Cartesian product of position, $\mathcal{A} \subseteq \{(i, j) : i = 1, \ldots, k; j = 1, \ldots, l\}$. Alignment results represented by $\mathcal{M}$ is defined as:

$$
\mathcal{M} = \begin{cases} 1 & (i,j) \in \mathcal{A} \\ 0 \leq a \leq 1 & \text{otherwise} \end{cases}
\tag{2}
$$

$\mathcal{M}$ is a penalty function over the similarity of unaligned tokens. It's a mask like matrix to assign a penalty weight a [2] to the similarity of unaligned tokens while keeping that of aligned ones unchanged, as illustrated in Figure 2. Thus, greedy matching is performed on a renewed similarity matrix, which is defined as the average of $\mathbf{x_i}^\top \hat{\mathbf{y}}_\mathbf{j}$ and masked $\mathbf{x_i}^\top \hat{\mathbf{y}}_\mathbf{j}$ by word alignment. For example, R_{BERT}

4	BERT (align+ppl)	0.132	**0.152**	**0.439**	**0.228**	0.320	-	0.247

Table 2: Kendall correlations with sentence-level Direct Assessment (DA) scores.

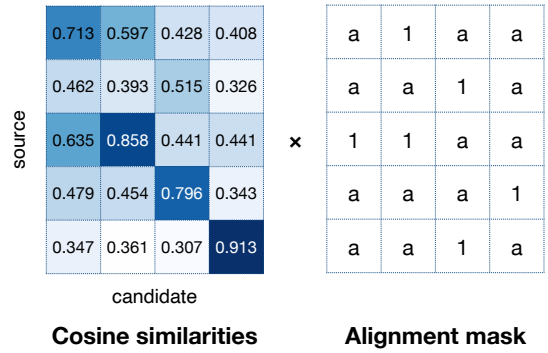

Figure 2: Word alignment as a mask matrix

is changed into:

$$R_{\text{BERT(align)}} = \frac{1}{2|x|}\sum_{x_i \in x} \max_{\hat{y}_j \in \hat{y}} (\mathbf{x_i}^\top \hat{\mathbf{y}}_\mathbf{j} + \mathcal{M} \cdot \mathbf{x_i}^\top \hat{\mathbf{y}}_\mathbf{j}) \tag{3}$$

which can be characterized as balancing our proposed extra explicit cross-lingual patterns, i.e., word alignment.

2.3 Generation Score

In additional to token similarity score, we introduce force-decoding perplexity of each target token as a cross-lingual generation score. For better coordination and considering our cross-lingual setting, we use the same pre-trained cross-lingual model, e.g. multilingual BERT, for both token embedding extraction and masked language model (MLM) perplexity generation. This cross-lingual generation score is added as:

$$F_{\text{BERT(ppl)}} = (1-\lambda) * F_{\text{BERT}} + \lambda * ppl_{\text{MLM}} \tag{4}$$

where the λ can be seen as a variable that regulates the interpolation ratio between F_{BERT} and our proposed ppl_{MLM}, making the generation score after combination more wisely. The effect of λ will be discussed in the experiments.

3 Experimental Results

3.1 Data

Main experiments were conducted on the WMT20 QE Shared Task, Sentence-level Direct Assessment language pairs. The task contains 7 directions, including:

- English→German (**en-de**)
- English→Chinese (**en-zh**)
- Romanian→English (**ro-en**)
- Estonian→English (**et-en**)
- Nepalese→English (**ne-en**)
- Sinhala→English (**si-en**)
- Russian→English (**ru-en**)

Each of them consists of 7K training data, 1K validation data and 1K test data.

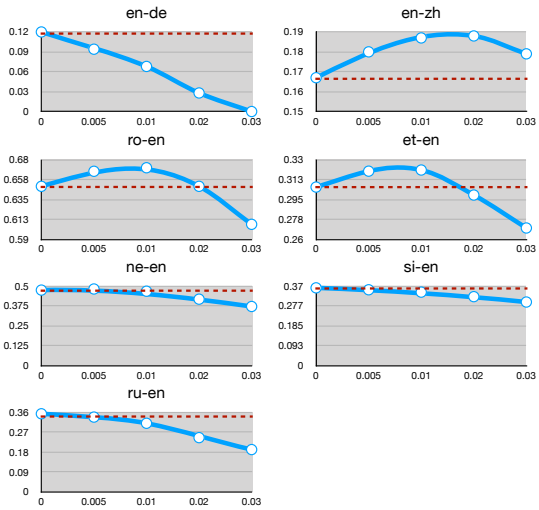

Figure 3: Pearson correlations with Direct Assessment (DA) scores when $\lambda \in [0, 0.03]$.

3.2 Setup

Based on our proposed QE metric in Section 2.1, we conduct the validataion and main experiments with two pre-trained cross-lingual model: bert-base-multilingual-cased[3] (12-layer, 768-hidden, 12-heads, trained on 104 languages) and xlm-mlm-100-1280[4] (16-layer, 1280-hidden, 16-heads, trained on 100 languages) for both contextual embedding representation and generation score. The 9th layer of multilingual BERT and the 11th of XLM are used to generate contextual embedding representations. Furthermore, we obtain bidirectional word alignment of all the training, validation and test dataset with GIZA++. Notably, this work is a zero-shot approach that doesn't involve training on Direct Assessment (DA) scores, which makes our method suitable for real industry scenarios.

3.3 Ablation Study

In order to maximize the advantages of our proposed method for zero-shot translation QE, we conducted extensive ablation studies. We report the results of ablation studies on the validation dataset.

Effect of λ We conduct ablation studies to empirically decide the value of of λ in Equation 4 when introducing generation scores. We observe positive effect of proper weighted additional generation score on **en-zh**, **ro-en**, **et-en**, **ne-en**, **si-en**.

[3] https://huggingface.co/bert-base-multilingual-cased

[4] https://huggingface.co/xlm-mlm-100-1280

	mBERT	XLM
en-de	0.120	0.056
en-zh	0.167	0.008
ro-en	0.650	0.568
et-en	0.306	0.254
ne-en	0.475	0.398
si-en	-	0.362
ru-en	0.354	0.228

Table 3: This is a comparison between multilingual BERT ("mBERT") and XLM in terms of the Pearson correlations with Direct Assessment (DA) scores. Multilingual BERT performs better than XLM.

As illustrated in Figure 3, considering the average performance, we pick $\lambda = 0.01$ from $[0, 0.03]$.

Effect of different pretrained models We also investigated the effect to deploy our proposed fixed cross-lingual patterns on different state-of-the-art large scale pre-trained models, e.g., XLM (Conneau and Lample, 2019) (xlm-mlm-100-1280), BERT (Zhang et al., 2020) (bert-base-multilingual-cased). Table 3 lists a comparison of multilingual BERT and XLM in terms of the Pearson correlations with Direct Assessment (DA) scores. As seen, multilingual BERT outperforms XLM on almost all language pairs, excepting for **si-en**. One possible reason is that multilingual BERT is not pre-trained on Sinhala corpus while XLM does. In this end, we generate our final submission with XLM in **si-en** direction, and with multilingual BERT in other directions.

3.4 Main Results

In the main experiments, we evaluate the agreement of our approach with Direct Assessment (DA) scores on validation dataset, as DA scores of the test set are not available at this point. Baseline results, which are evaluated on test set though, are also listed for general comparison.

As shown in Table 1, our method could achieve improvements on 4 out of 6 directions, including **en-zh**, **ro-en**, **et-en** and **ne-en**. Particularly, combination of two strategies, i.e., CROSS-LINGUAL ALIGNMENT and CROSS-LINGUAL GENERATION SCORE, could achieve better performance on **en-zh**, **ro-en** and **et-en** directions.

Besides Pearson correlations, we also calculated Kendall correlations for all language pairs. As seen in Table 2, the trends of Kendall correlations

	Ours	Kepler et al. (2019)
en-de	0.111	0.146
en-zh	0.085	0.190
ro-en	0.650	0.685
et-en	-	-
ne-en	**0.488**	0.386
si-en	**0.388**	0.374
ru-en	0.400	0.548

Table 4: Comparison of our submission and supervised baseline (Kepler et al., 2019) on WMT20 sentence-level QE official test set, in terms of Pearson correlations.

are same as Pearson correlations, validating the effectiveness of our proposed methods.

3.5 Official Evaluations

The official automatic evaluation results of our submissions for WMT 2020 are presented in Table 4. We participated QE (Sentence-Level Direct Assessment) in following language pairs: **en-de**, **en-zh**, **ro-en**, **ne-en**, **si-en**, **ru-en**, except for **et-en**. From the official evaluation results (Specia et al., 2020) in terms of absolute Pearson Correlation, our submission achieves higher performance than supervised baseline (Kepler et al., 2019) in **ne-en** and **si-en** (As shown in Table 4).

Encouragingly, our proposed zero-shot QE metric could achieve comparable performance with supervised QE method, and even outperforms the supervised counterpart on 2 out of 6 directions.

4 Related Work

MT evaluation Taking sentence-level evaluation as an example, reference-based metrics describe to which extend a candidate sentence is similar to a reference one (Sellam et al., 2020). BLEU (Papineni et al., 2002), METEOR (Banerjee and Lavie, 2005), NIST (Doddington, 2002), ROUGE (Lin, 2004) measure such similarity through n-gram matching, which is restricted to the exact form of sentences. TER (Snover et al., 2006) and CHARACTER (Wang et al., 2016b) use edit distance at word or character level to indicate the distance between candidate and reference. Different from these metrics that are restricted to the exact form of sentences, recent dominated neural model metrics *learn* to evaluate with human assessment as supervision signal, such as BEER (Stanojević and Sima'an, 2014) and RUSE (Shimanaka et al., 2018), or others as YiSi (Lo, 2019) and BERTScore (Zhang et al., 2020) , evaluate with pre-trained word embedding, without using human assessment.

Incorporating Explicit Knowledge Several approaches have incorporated pre-defined or learned features into neural networks. Tai et al. (2015) demonstrate that incorporating structured semantic information could enhance the representations. Sennrich and Haddow (2016) feed the encoder cell combined embeddings of linguistic features including lemmas, subword tags, etc. Ding et al. (2017) leverage the domain knowledge to perform data selection to improve the machine translation models. Ding and Tao (2019) incorporate the structure patterns of sentences, i.e., syntax, into the Transformer network to enhance seq2seq modeling performance. Raganato et al. (2020) utilize the pre-defined fixed patterns to replace the attention weights and show promising results. Inspired by above works, we propose to augment zero-shot QE model with cross-lingual patterns.

5 Conclusion and Future Work

In this work, we revealed a mismatching issue in zero-shot QE modeling. To alleviate it, we introduced two explicit cross-lingual patterns based on BERTScore backbone. Extensive experiments indicated that our proposed patterns, without fine-tuning, the QE model can be improved marginally. Notably, our zero-shot QE method outperforms supervised QE model on 2 out of 6 directions, shedding light on zero-shot QE researches.

In the future, we plan to explore more strategies for incorporating various auxiliary information and better in-domain fine-tuning (Gururangan et al., 2020) or introduce an non-autoregressive refiner (Wu et al., 2020) to address our revealed *mismatching issue*. Also, it will be interesting to apply QE metrics on document-level machine translations with considering the dropped pronoun (Wang et al., 2016a, 2018).

Abstract

This paper describes the results of the system that we used for the WMT20 very low resource (VLR) supervised MT shared task. For our experiments, we use a byte-level version of BPE, which requires a base vocabulary of size 256 only. BPE based models are a kind of sub-word models. Such models try to address the Out of Vocabulary (OOV) word problem by performing word segmentation so that segments correspond to morphological units. They are also reported to work across different languages, especially similar languages due to their sub-word nature. Based on BLEU cased score, our NLPRL systems ranked ninth for HSB to GER and tenth in GER to HSB translation scenario.

1 Introduction

We report the results for our system that was used for our participation in the WMT20 shared task (Barrault et al., 2019) on very low resource Machine Translation (MT). The MT systems were built for the language pair Upper Sorbian (HSB) and German (GER) in both translation directions.

The Sorbian languages are the West Slavic branch of the Indo-European languages, which have further categorized into two closely related languages, Upper Sorbian and Lower Sorbian. The categories of this language are recognized as a different and distinct language in the European Charter for Regional or Minority languages (Dolowy-Rybinska, 2011). Upper Sorbian is a minority language of Germany that is spoken by $10,000$ to $15,000$ speakers (Elle, 2010), although this number is continually declining (Dołowy-Rybińska, 2018). To counter this, attempts are being made to increase the number of Sorbian speakers through bilingual educational scenarios and MT[1].

[1] https://minorityrights.org/minorities/sorbs/

Low resource MT was being attempted even before Neural Machine Translation (NMT) became the state-of-the-art. Several methods are used to improve the accuracy and quality of the low-resource SMT systems by using comparable corpora (Irvine and Callison-Burch, 2013; Babych et al., 2007), pivot language (English or non-English) technique (Ahmadnia et al., 2017; Paul et al., 2013), and using related resource-rich language (Nakov and Ng, 2012).

We use a byte-level version of Byte Pair Encoding based model with a Transformer for our experiments. The main motivation was to try out this model for the shared task and see how it works under a shared task setting.

2 Background

NMT is an end-to-end learning system (Bahdanau et al., 2015), based on the data-driven approach of machine translation, that requires a massive amount of parallel data for training.

To overcome the lack of such data, several techniques have been tried out which are based on semi-supervised learning (Zheng et al. (2019)), unsupervised learning (Sun et al. (2020)), data augmentation (Siddhant et al. (2020)), transfer learning (Aji (2020)), meta-learning (Li et al. (2020)), pivot-based (Kim et al. (2019)), and multilingual machine translation (Dabre et al. (2020)).

A model-agnostic meta-learning algorithm (Finn et al., 2017) for low-resource NMT exploits the multilingual high-resource language tasks (Gu et al., 2018b). Gu et al. (2018a) achieved significant improvement in performance by utilizing a transfer-learning approach for extremely low resource languages.

Another proposed solution is to use word segmentation units, e.g. characters (Chung et al., 2016), mixed word/characters (Luong and Man-

Proceedings of the 5th Conference on Machine Translation (WMT), pages 1075–1078

ning, 2016), or more intelligent sub-words (Sennrich et al., 2016). It is claimed that an NMT model using such an approach is capable of open-vocabulary translation by encoding rare and unknown words as sequences of sub-word units.

The purpose of our experiments was to try out a supervised NMT system for the low resource language like HSB to GER and vice-versa for the WMT20 shared task.

3 System Description

The standard Transformer architecture proposed by Vaswani et al. (2017) is used for this experiment. This architecture is able to handle long-term dependencies among input tokens, output tokens and between input-output by multi-head attention mechanism. Our method based on the model architecture of Wang et al. (2020), which had used the **B**yte-level BPE (BBPE).

The BBPE encoding is deployed on the Byte Pair Encoding (BPE) (Sennrich et al., 2016), which is a subword algorithm to find a way to represent the given entire text dataset with a small number of tokens. BPE tries to find a balance between character- and word-level hybrid representations, enabling the encoding of any rare words in the vocabulary with appropriate subword tokens without introducing any "unknown" tokens. These segmented byte sequences are encoded into variable-length tokens, i.e., n-grams, which leads to the generation of the BPE vocabulary with byte n-grams. Before being fed to the Transformer model, the learned BBPE passes through bidirectional GRU, which enables to retain contextualization between byte representation of BPE.

4 Experimental Setup

We use the Fairseq[2] (Ott et al., 2019) library to train the Transformer with the same learning rate as in the original paper.

4.1 Dataset and Preprocessing

Our models were trained on the data provided by the Workshop on Machine Translation (WMT) 2020. The statistics about the training, validation and test sets are 60000, 2000 and 2000, respectively for both directional pairs (HSB - GER).

We obtained 1727916 and 1710293 tokens of the GER and HSB, respectively, from the train set for preprocessing. The BPE vocabulary, Byte vocabulary and Character vocabulary are 16384, 2048 and 4096, respectively, for generating binary dataset by using fairseq-preprocess. The BBPE used as a subword BPE tokenizer, where preprocessing was performed using lowercasing only. This is beneficial from the low resource point of view, but it loses the case information for German, which could have affected the results.

4.2 Training Details

We trained the Transformer model with Bi-GRU embedding, in which contextualization using the number of encoder and decoder layers are 2 with the dropout value 0.3. We trained our model with a batch size of 100, with the aid of Adam optimizer at 0.0005 learning rate. The learning rate has warmup update by 4000 to label smoothed cross-entropy loss function with label-smoothing value 0.1.

5 Results and Analysis

The BBPE based Transformer model was evaluated on the blind test set at five different metrics provided by the task organizer, namely BLEU (Papineni et al., 2002), BLEU-cased, TER (Snover et al., 2006), BEER2.0 (Stanojević and Sima'an, 2014), and CharacTER (Wang et al., 2016).

The obtained metrics score for each pair to each experiment is specified in Table 1. The prediction of the test set was generated by performing the best validation checkpoint. However, while comparing the BLEU score of the valid set with the test set, we obtained a difference of +3.21 for HSB→GER and +0.15 for GER→HSB pairs.

Before submitting the predictions of the test set, the BLEU scores of best and last checkpoints were almost equal, as shown in Table 2. Moreover, the vocabulary size plays a crucial role in data-driven approaches of MTs as well. Hence, we have increased the vocabulary size from 2048 to 4096 for generating BBPE, which led to a small decrement in the BLEU score. One possible reason for such decrement is the small vocabulary size that generates generalized BBPE for low-resource language.

6 Conclusion and future work

We have report the results for a Transformer-based MT system for the pair of HSB↔GER in very low resource settings. The introduced MT system works on Byte-level Byte Pair Encoding (BBPE), which yields 48.4 and 46.5 on HSB→GER and

[2] https://github.com/pytorch/fairseq

Pair	BLEU	BLEU cased	TER	BEER2.0	CharacTER
HSB-GER	48.4	47.9	0.383	0.706	0.335
GER-HSB	46.5	45.9	0.389	0.696	0.323

Table 1: Obtained scores of different metrics on the test set, provided by the task organizers

Vocab	Pair	Valid		Test
		Checkpoint (last)	Checkpoint (best)	Checkpoint (best)
2048	HSB-GER	45.92	45.19	48.4
	GER-HSB	46.62	46.35	46.5
4096	HSB-GER	45.77	45.09	-
	GER-HSB	46.96	46.24	-

Table 2: Effect on BLEU by increasing vocabulary size

GER→HSB, respectively, as the BLEU score on the test set at the vocabulary size of 2048. When the vocabulary size was increased from 2048 to 4096, lower performance was obtained on the system on either side of the pair on the validation set.

Abstract

We present our submission to the very low resource supervised machine translation task at the Fifth Conference on Machine Translation. The goal of this task is to create a system which translates between German and the low-resource language Upper Sorbian. We use a decoder-only transformer architecture and formulate the translation task as language modeling. To address the low-resource aspect of the problem, we pretrain over a similar language parallel corpus. Then, we employ an intermediate back-translation step before fine-tuning. Finally, we present an analysis of the system's performance.

1 Introduction

This work describes our system for translating in both directions between German (DE) and the low-resource language Upper Sorbian (HSB). German is a widespread language with tens of millions of speakers; Upper Sorbian is a West Slavic language spoken in Germany, and it is recognized as an endangered language by UNESCO (Moseley, 2010).

This system constitutes our submission to the shared task on very-low-resource supervised machine translation at WMT20.[1] The ultimate goal of the task is to translate a blind test set from Upper Sorbian into German and *vice versa*. The task is constrained, meaning that all data sets used for training are selected from a set of corpora provided by the organizers.

Our primary contribution is our application of a decoder-only language-modeling architecture to a low-resource translation task, which to our knowledge is not well-investigated.

In Sections 2 and 3, we discuss related work and our system itself. Sections 4, 5, and 6 describe our architecture. Sections 7 and 8 contain our results and analysis.

[1] http://www.statmt.org/wmt20

2 Related Work

Current approaches to machine translation include neural networks based on encoder-decoder transformers (Vaswani et al., 2017) and sequence-to-sequence models using recurrent networks (Chen et al., 2018). In both of these methods, the system learns how to produce an intermediate representation of a text sequence as a basis for the output translation. Language-neutral representations have been explored more deeply in the context of mBert (Libovický et al., 2019).

In the case of low-resource languages, where there is an absence of adequately sized parallel corpora, recent techniques focus on transfer learning (Zoph et al., 2016), relying on monolingual corpora (Lample et al., 2018), enriching the input to the system (Irvine and Callison-Burch, 2013), or expanding it through back-translation (Sennrich et al., 2016).

Techniques related to back-translation include pseudo-labeling and self-labeling. Pseudo-labeling uses partially accurate data for training (Ratner et al., 2017) generated from knowledge bases, heuristic functions and crowdsourcing. Self-labeling is an area that lies between self-supervised learning and pseudo-labeling (Caron et al., 2018; Asano et al., 2020). The model is used to predict labels for an unlabeled dataset and then is trained on this dataset.

3 Overview

Our system uses a transformer architecture, though instead of the traditional encoder-decoder layout, we use a single decoder-only transformer as do Radford et al. (2018), formulating the translation task as a language modeling task. This architecture was suggested by Radford et al. (2019) and explored concretely by Guo et al. (2019) for widely-used languages. Unlike previous approaches, in this method

Proceedings of the 5th Conference on Machine Translation (WMT), pages 1079–1083

there is no intermediate representation of the input; instead, the translation is predicted directly through the attention mechanism.

Furthermore, in our submission, we rely on a similar-language pretraining task with a shared vocabulary, using Czech (CS) / English (EN) sentence pairs, similarly to Kocmi and Bojar (2018) and Nguyen and Chiang (2017).

Finally, we supplement these techniques with traditional back-translation, using monolingual corpora in the target languages.

4 Data Preprocessing

4.1 Datasets

In this work, we only use datasets that were made available by WMT20:

- HSB/DE parallel corpus (60K pairs)
- Monolingual HSB data (600K sentences)
- Monolingual DE news data (600K sentence subset)
- CS/EN parallel news corpus (60M pairs)

For the initial pretraining, we use CS/EN parallel data. The unlabeled and labeled HSB/DE parallel data are used for the back-translation and fine-tuning steps.

In Section 8, we also show a comparison to a reference pretraining dataset: a CS/DE parallel corpus (1.6M pairs).

4.2 Preprocessing Method

Figure 1 shows the preprocessing of the training corpus. This method of preprocessing the corpus allows us to use a single decoder-only transformer and train it on a classical language modeling task.

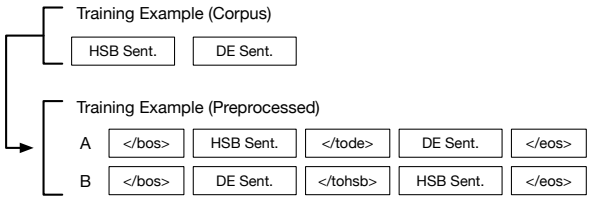

Figure 1: Preprocessing of the training corpus. The source and translation texts are concatenated with translation direction and beginning- and end-of-sequence tokens.

Since we use a CS/EN corpus on the initial pretraining step and HSB/DE corpora on the remaining steps, we create a joint byte-pair encoding which is generated by combining all of the corpora.

5 Training Method

Figure 2 shows the training method. In total, our method consists of five individual steps. These include: a pretraining step, an intermediate step made up of three sub-steps (a pre-fine-tuning step, back-translation, back-translated training), and a final fine-tuning step. The following subsections describe these steps in detail.

All of these steps (except the back-translation step, which is performed in inference mode) are performed as translation tasks using parallel corpora. The parallel corpora are either real or synthetic (in the case of the corpora resulting from back-translation).

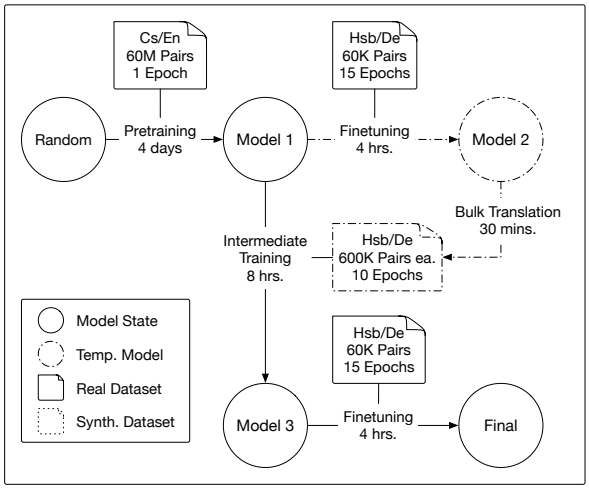

Figure 2: Training method: details are in Section 5. The dataset includes: CS/EN parallel (60M), HSB/DE parallel (60K), HSB/DE monolingal (600K each).

5.1 Initial Pretraining and Back-translation

We start by pretraining the model on a language translation task using a large (60M pair) parallel corpus consisting of Czech and English. As described by Kocmi and Bojar (2018), large (10M pair or above) parallel pretraining corpora provide significant performance gains. This is reinforced by our findings in Section 8.3.

Also, Czech and English are related to the the target languages, which can provide an additional performance benefit, according to Nguyen and Chiang (2017).

Figure 2 shows the pretraining on a CS/EN translation dataset and the first round of fine-tuning on the labeled data for the HSB/DE translation tasks.

In our method, we use the notion of *Model states*. After the pretraining step, the model reaches the *Model 1* state as depicted in Figure 2. At this step,

the model is fine-tuned and reaches the state *Model 2*. This state is used to back-translate the monolingual HSB/DE data into parallel corpora.

5.2 Back-Translated Training and Final Fine-Tuning

Output of the bulk translation is then saved and the *Model 2* state is discarded. The bulk translation is used as a parallel corpus for the back-translated training step beginning at the *Model 1* state: it consists of 600K pairs (per target language), whereby one sentence in the pair is from the monolingual corpus, and the other, parallel sentence is from the bulk translation output.

After the back-translated training, the model enters the *Model 3* state: this is the final state before the last fine-tuning. The last step is training the model in a supervised fashion on the labeled dataset.

One should note that, at this point, the model has not seen the labeled dataset yet. The state *Model 2* was trained on the labeled dataset but it is only used for the back-translation and discarded later. The final step trains the model using the highest-quality dataset: human-generated translations from the source language to the target language.

6 Implementation

We follow the GPT2 paper (Radford et al., 2019) for the model architecture, excepting hyperparameters. An overview of the system hyperparameters is shown in Table 1. We use layer normalization, a

Table 1: System Hyperparmeters

Hyperparameter	Value
Layers	4
Embedding Size	768
Attention Heads	12

standard dropout rate of 10%, and a learning rate of 5e-5 for all tasks. For the fine-tuning task, we employ L2 regularization. We train separate models for each translation direction. The total size of the model is 40M parameters.

Our choice of hyperparameters is based on a modified grid search over the attention heads, learning rate, layer count, and embedding size.

We used a single Nvidia GTX 1080TI GPU during training, and training times are shown in Figure 2. We argue that our method is time and resource efficient, easy to reproduce, and powerful.

7 Evaluation

In this section, we provide details about our implementation and the final results of the submitted system on the shared task: translation between German and Upper Sorbian.

7.1 Inference Versus Training

During the training tasks, we combine the source text, the target text, and control tokens. To use the resulting model to perform a translation of unfamiliar text, we use a slightly modified preprocessing step: we concatenate only the source text with a translation token. Since the model is trained to perform a classical language modeling task, it begins predicting the next token probabilities of the target text. We then apply beam search (with a beam width of five) to these tokens to arrive at the final translation.

7.2 Results

Table 2 shows the official BLEU score of our method on the blind test submission to WMT20. Submissions to the shared task ranged from 38.5 to 61.1 BLEU for DE to HSB translations and from 40.5 to 60.0 for HSB to DE translations.

In this section, all BLEU scores other than the blind test are calculated on the HSB/DE public test set and reference translations provided by WMT20.

Table 2: Our submission's results on the final blind test

Direction	BLEU
HSB-DE	46.0
DE-HSB	46.7

Table 3 shows a sample translation. The model's word choice is a slight generalization of the German reference, with correct grammar, spelling, and capitalization.

8 Analysis

8.1 Performance Breakdown

In order to understand the contribution of each training step to the final result, we performed experiments on different training sequences using the public HSB/DE test set provided by WMT20. The results of these experiments are reflected in Table 4. In the table, each step is cumulative and includes the steps above it: e.g., the "back-translation" step includes both fine-tuning and back-translation, but not pretraining.

Table 3: Sample Translation

Upper Sorbian Input
Otto Friedrich Bollnow mjenuje je tohodla tež hospodarske počinki.
Model output
Otto Friedrich Bollnow nennt sie deshalb auch wirtschaftliche Tugenden. **English** Therefore, Otto Friedrich Bollnow also names them economic virtues.
German Reference
Otto Friedrich Bollnow bezeichnet sie daher auch als wirtschaftliche Tugenden. **English** Therefore, Otto Friedrich Bollnow also describes them as economic virtues.

Table 4: Breakdown of BLEU score as training tasks are added: the results are cumulative

Step	DE-HSB	HSB-DE
Fine-tuning only	27.4	27.3
Back-translation	38.2	38.1
Pretraining	44.6	42.9
Blind test	46.7	46.0

We conclude from these experiments that the most significant gains came from back-translation (around 10 BLEU), followed by the pretraining step (4-6 BLEU).

For reference, we reiterate the blind test results in Table 2. The blind test results are different from the pretraining step due to differences in the data set.

8.2 Pretraining Task Selection

We considered using unsupervised learning as a pretraining task; however, a comparison of unsupervised pretraining in the target language with translation-task pretraining using related languages showed that the translation task had a greater impact on the final model's performance.

In this experiment, we compared the effect of different pretraining tasks on the model's translation performance. Recall that our architecture formulates the translation task as a language modeling task. Since the architecture acts as a language model, it is also possible to pretrain the model, without modification, on unsupervised text in the target languages.

To compare the unsupervised language modeling pretraining task with a translation pretraining task, we pretrained one model with the full HSB/DE unsupervised data set (600K sentences each, 10 epochs), a second model with a CS/DE parallel corpus (1.6M pairs, 3 epochs), and a third model with a subset of the CS/EN parallel corpus (60M pairs, 0.17 epochs), and then fine-tuned each of them using the supervised data set.

We compare these models to a baseline (fine-tuned only) model in Table 5. From these results, we conclude that the similar language translation tasks are more effective pretraining tasks than unsupervised language modeling in this context. The two related-language pretraining tasks were comparable in performance, though we only used a fraction of the CS/EN corpus due to its much larger size.

Table 5: Target-task BLEU score after fine-tuning, given pretraining tasks in various languages

Pretraining Task	Type	DE -HSB	HSB -DE
None	-	27.4	27.3
Unsupervised	HSB/DE	28.1	29.5
Translation	CS/DE	31.7	31.4
Translation	CS/EN	31.5	32.7

8.3 Pretraining Corpus Size

Finally, we examined the effect of the number of pretraining epochs on the final BLEU score. As shown in Table 6, roughly doubling the corpus size led to an increase of nearly 1.0 BLEU in the final model performance. This represents close to 20% of the performance increase we attribute to our pretraining task, which suggests that an even larger corpus, or additional pretraining epochs, would contribute further to model performance.

Table 6: Effect of 60M-pair pretraining corpus size (in epochs) on final HSB->DE BLEU score

Epochs	BLEU Score
0.42	41.4
1.00	42.3

9 Conclusion

Since our model produces high-quality translations, we have shown that a small decoder-only transformer, configured to perform classical language modeling, is an effective translation system for low-resource language pairs. Furthermore, we have shown that a similar language translation pretraining task can contribute substantially to the quality of such translation systems. Finally, we have provided an analysis of the model's components and their relative contribution to its ultimate performance.

Further investigation would be needed to understand our model's relationship to other architectures under the same data sets and pretraining tasks.

Acknowledgments

We would like to thank Prof. Eugene Charniak for the helpful discussion. We would also like to thank Prof. Ellie Pavlick for her help in reviewing the paper and the method.

Center for Information and Language Processing, LMU Munich, Germany
{achron, stojanovski, hangyav, fraser}@cis.lmu.de

Abstract

This paper describes the submission of LMU Munich to the WMT 2020 unsupervised shared task, in two language directions, German↔Upper Sorbian. Our core unsupervised neural machine translation (UNMT) system follows the strategy of Chronopoulou et al. (2020), using a monolingual pretrained language generation model (on German) and fine-tuning it on both German and Upper Sorbian, before initializing a UNMT model, which is trained with online backtranslation. Pseudo-parallel data obtained from an unsupervised statistical machine translation (USMT) system is used to fine-tune the UNMT model. We also apply BPE-Dropout to the low-resource (Upper Sorbian) data to obtain a more robust system. We additionally experiment with residual adapters and find them useful in the Upper Sorbian→German direction. We explore sampling during backtranslation and curriculum learning to use SMT translations in a more principled way. Finally, we ensemble our best-performing systems and reach a BLEU score of 32.4 on German→Upper Sorbian and 35.2 on Upper Sorbian→German.

1 Introduction

Neural machine translation achieves remarkable results (Bahdanau et al., 2015; Vaswani et al., 2017) when large parallel training corpora are available. However, such corpora are only available for a limited number of languages. UNMT addresses this issue by using monolingual data only (Artetxe et al., 2018c; Lample et al., 2018). The performance of UNMT models is further improved using transfer learning from a pretrained cross-lingual model (Lample and Conneau, 2019; Song et al., 2019). However, pretraining also demands large monolingual corpora for both languages. Without abundant data, UNMT methods are often ineffective (Guzmán et al., 2019). Therefore, effectively translating between a high-resource and a low-resource language, in terms of monolingual data, which is the target of this year's unsupervised shared task, is challenging.

We participate in the WMT 2020 unsupervised machine translation shared task. The task includes two directions: German→Upper Sorbian (De→Hsb) and Upper Sorbian→German (Hsb→De). Our systems are constrained, using only the provided Hsb monolingual data and De NewsCrawl monolingual data released for WMT. We pretrain a monolingual encoder-decoder model on a language generation task with the Masked Sequence to Sequence model (MASS) (Song et al., 2019) and fine-tune it on both languages of interest, following Chronopoulou et al. (2020). We then train it on UNMT, using online backtranslation. We use our USMT system to backtranslate monolingual data in both languages. This pseudo-parallel corpus serves to fine-tune our UNMT model. Iterative offline backtranslation is later leveraged, yielding a performance boost. We use BPE-Dropout (Provilkov et al., 2020) as a data augmentation technique, sampling instead of greedy decoding in online backtranslation, and curriculum learning to best include the SMT pseudo-parallel data. We also use residual adapters (Houlsby et al., 2019) to translate to the low-resource language (Hsb).

Results Summary. The ensemble of our best-performing systems yields the best performance in terms of BLEU[1] among the participants of the unsupervised machine translation shared task. We release the code and our best models[2] in order to facilitate reproduction of our work and experimentation in this field. We note that we have built upon

The numbers in gray correspond to the rows of Table 1. `Online BT` refers to the backtranslation of sentences with the actual model and updating it with the generated pseudo-parallel data. `Pseudo-SMT` refers to data obtained by backtranslating using the USMT baseline system while pseudo-NMT to our translations using system 5. The components of our approach are explained in Section 2.

the MASS codebase[3] for our experiments.

2 Model Description

Figure 1 presents all the different components of our system and how they are connected to each other. We train both an unsupervised SMT (#1) and NMT (#2) model. The UNMT model is based on a pretrained MASS model (#0), which is *monolingual* (`De`). The model is later fine-tuned on both `Hsb` and `De`. We additionally explore fine-tuning only on `Hsb` using adapters. These models are used to initialize an NMT model (#2, #4) which is trained with online backtranslation. We additionally experiment with sampling (#3) during backtranslation. The USMT model is used to backtranslate `Hsb` and `De` data. This synthetic bi-text is used to fine-tune the baseline UNMT model (#5). We use the synthetic bi-text also to fine-tune directly the adapter-augmented MASS model, while employing online backtranslation and sampling (#8). We experiment with curriculum learning (#6) to estimate the optimal way to feed the model this pseudo-parallel data. We also use our UNMT model to generate backtranslations and fine-tune existing models (#7). Further USMT-backtranslated data is used in #9. Finally, some models are fine-tuned with monolingual data which is oversampled and segmented with BPE-Dropout (#10, #11). The details of these components are outlined in the following.

2.1 Unsupervised SMT

First we describe the USMT system which we use to generate pseudo-parallel data to fine-tune our NMT system. We use *monoses* (Artetxe et al., 2018b), which builds unsupervised bilingual word embeddings (BWEs) and integrates them to Moses (Koehn et al., 2006), but apply some modifications to it.

As a first step, we build unsupervised BWEs with *fastText* (Bojanowski et al., 2017) and *VecMap* (Artetxe et al., 2018a) containing representations of 1-, 2- and 3-grams. Since the size of the available monolingual `Hsb` data is low, mapping monolingual embeddings to BWEs without any bilingual signal fails, i.e., we find no meaningful translations by manually investigating the most similar cross-lingual pairs of a few words. Instead, we rely on identical words occurring in both `De` and `Hsb` corpora as the initial seed dictionary. The BWEs are then converted to phrase-tables using cosine similarity of words and a language model is trained on the available monolingual data. The shared task organizers released a validation set which we use to tune the parameters of the system with MERT, instead of running unsupervised tuning as described in Artetxe et al. (2018b). Finally, we run 4 itera-

[3] https://github.com/microsoft/MASS

tive refinement steps to further improve the system. Other than the above, all steps and parameters are unchanged.

We use this system in inference mode to back-translate 7M De and 750K Hsb sentences. We refer to this pseudo-parallel dataset as 7.7M SMT pseudo-parallel. We also backtranslate 10M more De sentences. This dataset is later used to fine-tune one of our systems. We refer to it as 10M Hsb-De SMT pseudo-parallel.

2.2 MASS

We initialize our UNMT systems with an encoder-decoder Transformer (Vaswani et al., 2017), which is pretrained using the MASS (Song et al., 2019) objective. The model is pretrained by trying to reconstruct a sentence fragment given the remaining part of the sentence. The encoder takes a randomly masked fragment as input, while the decoder tries to predict the masked fragment. MASS is inspired by BERT (Devlin et al., 2019), but is more suitable for machine translation, as it pretrains the encoder-decoder and the attention mechanism, whereas BERT is an encoder Transformer. In order to pretrain the model, instead of training MASS on both De and Hsb, we initially train it on De. After this, we fine-tune it on both De and Hsb, following RE-LM (Chronopoulou et al., 2020). The intuition behind this is that, if we simultaneously train a cross-lingual model on unbalanced data, where X is much larger than Y, the model starts to overfit the low-resource side Y before being trained on all the high-resource language data (X). This results in poor translations. We refer to our pretrained model as FINE-TUNED MASS.

2.2.1 Vocabulary Extension for NMT

To fine-tune the pretrained De MASS model on Hsb, we need to overcome the following issue: the pretrained model uses BPE segmentation and vocabulary based only on De. To this end, we again follow RE-LM. We denote these BPE tokens as BPE_{De} and the resulting vocabulary as V_{De}. We aim to fine-tune the monolingual MASS model to Hsb. Splitting Hsb with BPE_{De} would result in heavy segmentation of Hsb words. To prevent this from happening, we learn BPEs on the joint De and Hsb corpus (BPE_{joint}). We then use BPE_{joint} tokens to split the Hsb data, resulting in a vocabulary V_{Hsb}. This method increases the number of shared tokens and enables cross-lingual transfer of the pretrained model. The final vocabulary is the union of the V_{De} and V_{Hsb} vocabularies. We extend the input and output embedding layer to account for the new vocabulary items. The new parameters are then learned during fine-tuning.

2.3 Adapters

Besides initializing our UNMT systems with FINE-TUNED MASS, we also experiment with pretraining MASS on De and fine-tuning *only* on Hsb. During fine-tuning, we freeze the encoder and decoder Transformer layers and add adapters (Houlsby et al., 2019) to each of the Transformer layers. Adapters can prevent catastrophic forgetting (Goodfellow et al., 2013) and show promising results in various tasks (Bapna and Firat, 2019; Artetxe et al., 2020). We fine-tune only the output layer, the embeddings and the decoder's attention to the encoder as well as the lightweight adapter layers.

We investigate adapters as fine-tuning in this way is considerably more computationally efficient. We also experimented with freezing the decoder's attention to the encoder as well as adding an adapter on top of it, but these architecture designs are worse in terms of perplexity during MASS fine-tuning as well as BLEU scores during UNMT.

We use the fine-tuned model to initialize an encoder-decoder Transformer, augmented with adapters. The adapter-augmented model is then trained in an unsupervised way, using online back-translation. All layers are trainable during unsupervised NMT training. We refer to this model as FINE-TUNED MASS + ADAPTERS.

2.4 Unsupervised NMT (online backtranslation)

We initialize our UNMT models with FINE-TUNED MASS. Following Song et al. (2019), we train the systems in an unsupervised manner, using online backtranslation (Sennrich et al., 2016a) of the monolingual Hsb and De data, that were also used for pretraining. As proposed in Song et al. (2019), we do not use denoising auto-encoding (Vincent et al., 2008). We use online backtranslation to generate pseudo bilingual data for training. We refer to the resulting model as UNMT BASELINE.

2.5 Sampling

We experiment with sampling instead of greedy decoding during online backtranslation. Edunov et al. (2018) show that sampling is beneficial for backtranslation compared to greedy decoding or beam search for systems trained on larger amounts

of parallel data. Although we do not use any parallel data, we assumed that our initial UNMT baseline is of reasonable quality and that sampling would be beneficial. However, in order to provide a balance, we randomly use either greedy decoding or sampling during training. The frequency with which sampling is used is a hyperparameter which we set to 0.5. Sampling temperature is set to 0.95.

2.6 Curriculum learning

Considering the high improvements achieved by including SMT backtranslated data, we conduct experiments to determine a more meaningful way to feed the data to the model using curriculum learning (Kocmi and Bojar, 2017; Platanios et al., 2019; Zhang et al., 2019). We learn the curriculum using Bayesian Optimization (BO) for which we use an open source implementation[4]. Similar work has been proposed for transfer learning (Ruder and Plank, 2017) and NMT (Wang et al., 2020). As we already have a reasonably trained NMT model, we use it to compute instance-level features for learning the curriculum. Each sentence pair from the SMT backtranslated data is represented with two features: the model scores for this pair in the *original* (backtranslation → monolingual sentence) and *reverse* direction (monolingual → backtranslation).

The weights that determine the importance of these features are learned separately for De→Hsb and Hsb→De, so that we have 4 features in total. BO runs for 30 trials. The feature weights are constrained in the range $[-1, 1]$. Each trial runs 5.4K NMT updates. The curriculum optimizes the sum of Hsb→De and De→Hsb validation perplexity. For the optimization trials, we only use the SMT backtranslated data as pseudo-parallel data and do not use online backtranslation. Finally, based on the feature weights and the features for each sentence, we sort the pseudo-parallel data and fine-tune the UNMT BASELINE with SMT backtranslations and online backtranslation. It would be interesting to study if a similar approach can be used to estimate a more optimal loading of monolingual data during MASS pretraining and UNMT.

2.7 Offline Iterative Backtranslation

We also experiment with creating synthetic training data using offline backtranslation with one of our UNMT systems (#5 in Table 1). We translate 750K De sentences to Hsb and 750K Hsb sentences to De. The resulting pseudo-parallel system is denoted as `750K NMT pseudo-parallel` corpus and is used to fine-tune the same system.

2.8 BPE-Dropout

BPE segmentation is useful in machine translation, as it efficiently addresses the open vocabulary problem. This approach keeps the most frequent words intact and splits the rare ones into multiple tokens. It builds a vocabulary of subwords and a merge table, specifying which subwords have to be merged and the priority of the merges. BPE segmentation always splits a word deterministically. Introducing stochasticity to the algorithm (Provilkov et al., 2020), by simply removing a merge from the merges with a pre-defined probability p, results in significant BLEU improvements for various languages in low- and medium-resource datasets.

We use BPE-Dropout in the following way: we oversample the Hsb monolingual data by a factor of 10 and apply BPE-Dropout. In that way, we get different segmentations of the same sentences and feed this data to the model. We also oversample the `750K SMT pseudo-parallel` corpus in the same manner, but only apply BPE-Dropout to the Hsb side. These monolingual and pseudo-parallel oversampled datasets are used to fine-tune our models. These systems perform better than our other single systems.

2.9 Ensembling

For the final models, we perform ensemble decoding with the best training models obtained in our experiments. We evaluate several combinations of model ensembles. Based on BLEU scores on the test set provided during development, we decide on two separate ensembles for De→Hsb and Hsb→De for the final submission.

3 Experiments

3.1 Data Pre-processing

In line with the rules of the WMT 2020 unsupervised shared task[5], we used 327M sentences from WMT monolingual News Crawl[6] dataset for German, collected over the period of 2007 to 2019. We also used the Upper Sorbian side of the provided parallel data as well as all of the monolingual data, a total amount of 756K sentences, provided by the

Table 1: BLEU scores of UMT for De-Hsb and Hsb-De systems. The systems with the underlined results were ensembled and used in our primary submissions. #12 is our primary system submitted to the organizers in the De→Hsb direction, while #13 is our primary system submitted in the Hsb→De direction. 6* was trained after the shared task and is not used for the final submission.

organizers. We used the provided parallel data for validation/testing (2K/2K sentences). We normalized punctuation, tokenized and true-cased the data using standard scripts from the Moses toolkit (Koehn et al., 2006). We note that we tokenized Hsb data using Czech as the language of tokenization, since these two languages are very closely related and there are no tokenization rules for Hsb in Moses.

We used BPE (Sennrich et al., 2016b) segmentation for our neural system. Specifically, we learned 32K codes and computed the vocabulary using the De data. We then also learned the same amount of BPEs on the joint corpus (De, Hsb) and computed the joint vocabulary. We extended the initial vocabulary, adding to it unseen items. We used this augmented vocabulary to fine-tune the MASS model and run all the UNMT training experiments.

3.2 Data Post-processing

We fixed the quotes to be the same as in the source sentences (German-style). We also applied a recaser using Moses (Koehn et al., 2006) to convert the translations to mixed case.

3.3 Training

Unsupervised SMT. As mentioned before, we used *fastText* (Bojanowski et al., 2017) to build 300 dimensional embeddings on the available monolingual data. We build BWEs with *VecMap* (Artetxe et al., 2018a) using identical words as the seed dictionary and restricting the vocabulary to the most frequent 200K, 400K and 400K 1-, 2- and 3-grams respectively. We used *monoses* (Artetxe et al., 2018b) as the USMT pipeline but used the available validation data for parameter tuning and ran 4 iterative refinement steps.

MASS. We use a Transformer, which consists of 6-layer encoder and 6-layer decoder with 1024 embedding/hidden size, 4096 feed-forward network size and 8 attention heads. We pretrain MASS on De monolingual data, using Adam (Kingma and Ba, 2015) optimizer with inverse square root learning rate scheduling and a learning rate of 10^{-4}. We used a per-GPU batch size of 32. We trained the model for approximately 2 weeks on 8 NVIDIA GTX 1080 Ti 11 GB GPUs. The rest of the hyperparameters follows the original MASS paper. We fine-tune MASS on both De and Hsb using the same setup, but on 4 GPUs of the same type. Fine-tuning was performed for 2 days.

Unsupervised NMT. For unsupervised NMT, we further train the fine-tuned MASS using online backtranslation. We use 4 GPUs to train each one of our UNMT models. We report BLEU using SacreBLEU (Post, 2018)[7] on the provided test set.

Unsupervised NMT + Pseudo-parallel MT. We train our UNMT systems using a pseudo-parallel supervised translation loss, in addition to the online backtranslation objective. We found out that aug-

[7] BLEU+case.mixed+numrefs.1+smooth.exp+tok.13a+version.1.4.13

menting UNMT systems with pseudo-parallel data obtained by USMT leads to major improvements in translation quality, as previous work has showed (Artetxe et al., 2018b; Stojanovski et al., 2019).

4 Results

The results of our systems on the test set provided during development are presented in Table 1. Our USMT model (#1) performs competitively, but is largely outperformed by the UNMT baseline (#2). These results are interesting considering that both systems are trained using small amounts of monolingual Hsb data. We believe that the performance of the UNMT model is largely due to the MASS fine-tuning scheme which allowed us to obtain a strong pretrained model for both languages. We also observe (#3) that mixing greedy decoding and sampling during backtranslation is beneficial compared to always using greedy decoding (#2), especially for De →Hsb which improved by 1.0 BLEU. However, it is likely that sampling is useful only if the model is of reasonable quality. We note that the adapter-augmented model (#4) is worse than the UNMT baseline.

After these initial experiments, we use the USMT model (#1) to backtranslate all Hsb monolingual data and 7M De sentences. This pseudo-parallel data is leveraged to fine-tune our UNMT models alongside online backtranslation. This approach, denoted as model #5, improves the UNMT baseline (#3) by more than 5.5 BLEU for De→Hsb and 4.5 BLEU for Hsb→De. The curriculum learning approach (#6) yields a small improvement of 0.6 BLEU for Hsb→De. Unfortunately, the curriculum learning model ran without the use of sampling. We later train the model with sampling (#6*) and obtain slight improvements in both directions.

Using NMT backtranslations in an offline manner (#7) provides for a large improvement in the Hsb→De direction, obtaining 33.2 BLEU. Further training our high scoring model #7 on USMT backtranslations, depicted as model #9, degrades performance on Hsb→De. This might indicate that USMT backtranslations alone are not very important for high performance, but simply adding any kind of pseudo-parallel data during training.

The adapter-augmented model with USMT backtranslations (#8) manages to close the gap to the baseline model. Comparing #5 and #8, we can see that the model with adapters is worse by 0.9 BLEU on De→Hsb, but better by 0.4 on Hsb→De. Due to time constraints, we train #4 and #8 in parallel and #8 is not fine-tuned from #4. Overall, adapters are a promising research direction as they lead to faster MASS fine-tuning and comparable performance.

We observe considerable improvements using BPE-Dropout. As noted before, we oversample the parallel and Hsb monolingual data and apply BPE-Dropout only on Hsb. We use this data to fine-tune some of our already trained models, specifically #5 and #7 which results in models #10 and #11, respectively. This approach improves the Hsb→De direction by up to 1.5 BLEU and up to 1.0 BLEU for De→Hsb. System #11 proved to be our best single system in both translation directions. We hypothesize that using BPE-Dropout while simultaneously oversampling the data provides for a data augmentation effect. In future work, it would be interesting to decouple these two steps and measure their effect separately.

Ensembling further boosts performance. Ensemble #12 is used for De→Hsb and #13 for Hsb→De. We note that while computing ensemble BLEU scores during development, we did not fix the issue with German-style quotes. This resulted in ensemble #13 obtaining better scores on Hsb→De. We later fix the quotes issue and find out that ensemble #12 is better on both translation directions and is the best system overall.

5 Conclusion

In this paper, we present the LMU Munich system for the WMT 2020 unsupervised shared task for translation between German and Upper Sorbian. Our system is a combination of an SMT and an NMT model trained in an unsupervised way. The UNMT model is trained by fine-tuning a MASS model, according to the recently proposed RE-LM approach. The experiments show that the MASS fine-tuning technique is efficient even if little monolingual data is available for one language and results in a strong UNMT model. We also show that using pseudo-parallel data from USMT and UNMT backtranslations improves performance considerably. Furthermore, we show that oversampling the low-resource Upper Sorbian and applying BPE-Dropout, which can effectively be seen as data augmentation, results in further improvements. Adapters in MASS fine-tuning provided for a balance between performance and computational efficiency. Finally, smaller but noticeable gains are obtained from us-

ing curriculum learning and sampling during decoding in backtranslation.

Abstract

This paper describes the UdS-DFKI submission to the shared task for unsupervised machine translation (MT) and very low-resource supervised MT between German (de) and Upper Sorbian (hsb) at the Fifth Conference of Machine Translation (WMT20). We submit systems for both the supervised and unsupervised tracks. Apart from various experimental approaches like bitext mining, model pretraining, and iterative back-translation, we employ a factored machine translation approach on a small BPE vocabulary.

1 Introduction

This paper describes the UdS-DFKI submission to the unsupervised and very low resource supervised tasks of WMT20 for German to Upper Sorbian (*de→hsb*) and Upper Sorbian to German (*hsb→de*). Our submitted systems are constrained for the very low resource supervised and unconstrained for the unsupervised task, in that we use Wikipedia dumps as additional data.

Current machine translation systems that deal with low-resource languages are based on unsupervised neural machine translation, semi-supervised methods and pre-trained models leveraging monolingual data (Guzmán et al., 2019), and multilingual systems among others. In this work, we explore different systems which include baseline NMT, factored NMT (Sennrich and Haddow, 2016a), iterative backtranslation, self-supervised NMT (SSNMT) (Ruiter et al., 2019) and pretraining with XLM (Lample and Conneau, 2019) using transformer-base models (Vaswani et al., 2017) for the training of the systems.

This paper begins by presenting the data we used for the tasks and the preprocessing pipeline (Section 2). This is followed by an overview of the training setup (Section 3) and the methods we applied (Section 4). Section 5 summarizes our findings, followed by a discussion of the results in Section 6. We conclude the paper and propose some possible future work in Section 7.

2 Data

Unsupervised Task For Sorbian, we use the given data from the Sorbian Institute (Ins_{hsb}), from Witaj Sprachzentrum (Witaj_{hsb}), and web-scraped data (Web_{hsb}). Table 1 gives a summary of the data we use in the unsupervised track. We use the Europarl (EP_mono_{de}, (Koehn, 2005)) and News Commentary (NC_mono_{de}, (Barrault et al., 2019)) datasets for the monolingual German data. Apart from this, we also use Wikipedia Dumps[1] for both German and Upper Sorbian. We extract articles using Wikiextractor[2], which are aligned using Wikipedia *langlinks*[3] to create a comparable corpus for SSNMT extraction.

Supervised Task Apart from the provided parallel data, we use high-quality EUROPARL (EP, (Koehn, 2005)) and medium-quality JW300 (Agić and Vulić, 2019; Tiedemann, 2012) corpora for *de-cs-hsb*. For parallel text mining with LASER (Schwenk, 2018; Artetxe and Schwenk, 2019), we use the combination of all the monolingual corpora of German and Upper Sorbian from the unsupervised section of Table 1, which is discussed in detail later in Section 4.3.

Preprocessing Our preprocessing steps include normalization, tokenization, deduplication, and truecasing. We attach feature labels related to the source language (<src>), target language (<tgt>), and the data quality (<quality>), for

every individual sentence. The quality of a sentence depends on the corpus it is from and the quality tags of <low>, <medium>, or <high> are added to all sentences of the corpora according to the quality labels assigned to the data provided for the shared task: e.g. Ins_{hsb} is high quality Sorbian. A typical sentence from the corpus after our preprocessing pipeline has the following format:

```
<src> <tgt> <quality> sentence
```

After factoring (4.2), we proceed to apply joint byte-pair encoding (BPE) (Sennrich et al., 2016b) on the corpora to finally get our preprocessed data which we use for training all our NMT models. Unless specified otherwise, we use a default of 5k merge operations.

3 Systems

MT Systems We train all our models using the Transformer-base architecture in the OpenNMT-py (Klein et al., 2017) framework extended for SSNMT[4] (Ruiter et al., 2019). The setting for the Transformer base is the same as in Vaswani et al. (2017) with 6 encoder-decoder layers after having explored other options of Transformer depth. We set the dropout to 0.4 in all experiments. We use *adam* (Kingma and Ba, 2014) for optimization with $\beta_1 = 0.9$ and $\beta_2 = 0.998$. The learning rate is varied from 0 to 2 with a warm update of 4000 and decayed using *noam*. Lower values of learning rate were avoided due to slower training and lower accuracy scores. We use a batch size of 50. The Phrase-Based Statistical MT systems (PBSMT) are standard *Moses* (Koehn et al., 2007) systems trained without applying BPE to the data.

Initialization The NMT models are initialised with cross-lingual word embeddings calculated on the monolingual corpora using `word2vec`[5] (Mikolov et al., 2013) (skip-gram) and unsupervised `VecMap`[6] (Artetxe et al., 2017).

Pre-trained Sentence Representations For XLM (Lample and Conneau, 2019), we pre-train and fine-tune the model using drop out of 0.1, batch size of 32 with a joint BPE of $10k$ ($10k$ showed better results for XLM), learning rate of 0.0001, and a sequence length of 265 using 512 and 1024 embedding dimensions respectively.

Evaluation Metric We use BLEU[7] (Papineni et al., 2002) scores to evaluate the performance of our trained models.

4 Techniques

4.1 Iterative Backtranslation

For the unsupervised task, we use an SSNMT system as described in Ruiter et al. (2019) to extract parallel sentences from the Wikipedia dumps. SSNMT jointly and iteratively extracts parallel data, and learns the MT task on the extracted parallel data. The resulting trained NMT model is our base model (M_0).

For iterative back-translation (Hoang et al., 2018), we take a model M_i and use it to translate the *hsb* monolingual data mono_{hsb} and EP_mono_{de} to generate mono^i_{de} and EP_mono^i_{hsb} respectively. Following Sennrich et al. (2016a), we use the generated data at iteration i on the source side with

[7] We use the *Moses* multi-bleu script for evaluation. https://github.com/moses-smt/mosesdecoder/blob/master/scripts/generic/multi-bleu.perl

the original data on the target to train a new model M_{i+1}. This is done iteratively, in our case until $i = 5$.

As the translation quality of M_0 is very low, this model is replaced by a PBSMT system which is trained on the data that M_0 has extracted, in order to generate the back-translation to be used for M_1.

Model	BLEU	
	hsb→de	*de→hsb*
M_0	6.46	6.09
M_1	8.53	8.31
M_2	9.81	10.04
M_3	10.47	13.51
M_4	**11.31**	11.57
M_5	9.13	**13.61**

Table 2: BLEU scores of iterative-backtranslation models per iteration, calculated on Dev20.

The resulting BLEU scores on Dev20 for each of the iterations is shown in Table 2. The best performance for *hsb→de* is achieved at $i = 4$ (11.31 BLEU) and for *de→hsb* at $i = 5$ (13.61 BLEU). These constitute two of the models submitted to the unsupervised task.

4.2 Factorization

Limited monolingual language analysis tools and few linguistic analysis tools with acceptable performance are available for low-resource (LowRes) languages. In our experiments, we explore factored machine translation (García-Martínez et al., 2016; Sennrich and Haddow, 2016b; Koehn and Knowles, 2017). This approach can play a significant role in increasing grammatical coherence. Syntactic and semantic information can be useful to generalize neural models trained on parallel corpora.

We augment our parallel data to include factors like *lemma* (using Snowball Stemmer (Porter, 2001)) and *PoS* tags (using *spaCy*[8] open source library (Honnibal and Montani, 2017)) for German words. The language-agnostic UDPipe trainable pipeline (Straka et al., 2016) has been used for lemmatization and PoS tagging for Sorbian words. We follow an approach similar to Bandyopadhyay (2019, 2020), where we factor the data at word-level to include the root word (*lemma*) and the part of speech (*PoS*) of each word along with the word itself, each component separated with a pipe (|) symbol.

```
word_token | lemma | PoS
```

Byte-pair encoding is implemented after factorization. After training the model, the test dataset on the source side of the language pair is used to obtain the output dataset on the target side of the language pair. Once testing is done, the data is again decoded using the trained BPE model before.

For the **supervised** task, we submit a German to Upper Sorbian factorized model on the German side of the parallel corpus which resulted in 40.9 and 40.3 cased BLEU score.

For the **unsupervised** task, Upper Sorbian to German factorization on the best-performing SS-NMT model improves the BLEU score by 0.1 to 9.0 on Test20 in comparison to the non-factorized model.

The results of the factored models are reported in Tables 3 (supervised) and 4 (unsupervised).

BPE	de (fac.)→hsb	hsb (fac.)→de
2k	31.01	37.09
5k	**41.15**	32.17
10k	35.67	**38.23**
20k	34.70	37.62

Table 3: Supervised Source Factored NMT systems with BLEU scores on DevTest20.

System	BLEU
de→hsb (fac.)	5.67
de (fac.)→hsb (fac.)	6.03
hsb→de (fac.)	7.24
hsb (fac.)→de (fac.)	**7.49**

Table 4: Unsupervised Factored NMT systems with BLEU scores for 10k BPE on DevTest20.

4.3 Data Mining with LASER

We use LASER (Schwenk, 2018; Artetxe and Schwenk, 2019) to filter and mine parallel sentences from a list of monolingual corpora of both German and Upper Sorbian. For German, we use the Wiki_{de}, EP_mono_{de}, and NC_{de} corpora, while

[8] https://github.com/explosion/spaCy

for the Upper Sorbian counterpart, we use the monolingual corpora Ins_{hsb}, Witaj_{hsb}, Web_{hsb}, and Wikipedia dumps (Wiki_{hsb}) as mentioned in Table 1. We explore a range of LASER extraction threshold values (1.03, 1.04, 1.05, 1.06, and 1.07) for this process. Table 5 gives a summary of the number of parallel sentences extracted from the monolingual corpora combinations from both languages using different threshold values. Using a lower threshold value extracts a higher number of parallel sentences but the quality gradually deteriorates as the threshold value decreases. We train NMT models on parallel sentences from each threshold and find that 1.04 gives comparatively better results than others. We use the model M_4 from iterative backtranslation (Table 2) as the baseline and then add the extracted sentences to check if the performance improves. However, all the resulting BLEU scores using additional LASER data are much lower than those of the iterative backtranslation baseline models reported in Table 2, indicating poor quality of the LASER extractions.

Threshold	# Sentences
1.03	18,979
1.04	**9,609**
1.05	5,200
1.06	2,806
1.07	1,646

Table 5: Number of parallel sentences mined using LASER with different threshold values.

4.4 Pre-training with Cross-lingual Language Model XLM

We explore the option of using pre-trained models with different embedding sizes to improve the performance of our system in the unsupervised task. We collected the sentence pairs from Wikipedia extracted with SSNMT. Also we collected back-translations for the monolingual data provided for the task using iterative backtranslation as explained in Section 4.1. We then pre-train XLM for de-hsb using all the monolingual data except Wiki_{de} and Wiki_{hsb}. We then fine-tune the pre-trained model for the supervised translation task using the parallel data from M_0 and back-translations taken from M_4 and M_5. Table 6 shows the resulting BLEU scores for this task on Dev20 and DevTest20.

XLM Embedding Size	BLEU	
	hsb→de	*de→hsb*
Dev20		
512	8.84	**8.41**
1024	**8.91**	8.15
DevTest20		
512	**7.58**	**7.29**
1024	7.44	6.78

Table 6: BLEU scores of pre-training with XLM on Dev20 and DevTest20.

5 Results

Tables 7 (submitted systems) and 8 (unfactored baseline systems) show a summary of all BLEU scores.

Model	BLEU		
	Dev20	DevTest20	Test20
Unsupervised			
de→hsb	13.6	9.9	10.3
hsb→de	11.3	8.1	8.9
hsb (fac.)→de	9.8	8.7	9.0
Supervised			
de (fac.)→hsb	44.34	41.15	40.9

Table 7: BLEU scores for the submitted models on the Dev20, DevTest20, and Test20 datasets.

Unsupervised Parallel data extracted with self-supervised NMT on Wikipedia dumps data and iterative back-translation on mono_{hsb} EP_mono_{de} were used to train the models. For the unsupervised track, we submit three NMT models trained in the directions from unfactored German to unfactored Upper Sorbian (*de→hsb*), from unfactored Upper Sorbian to unfactored German (*hsb→de*), and from factored Upper Sorbian to unfactored German (*hsb*(fac.)*→de*). The iterative backtranslation model M_5 (Table 2) for *de→hsb* obtains a BLEU score of **9.0** on the WMT blind test data. The *hsb→de* model (M_4 in Table 2) achieves a BLEU score of **8.9** while the same model with a factored Upper Sorbian source slightly pushes the BLEU score to **9.0**.

Supervised For the supervised task, we submit a single *de*(fac.)→*hsb* NMT model (refer Table 3) where the German side is factored. The model achieves a BLEU score of **40.9** on the WMT blind test data.

6 Discussion

System	BPE	de→hsb	hsb→de
PBSMT		36.93	37.65
bilingual de-hsb	2k	**41.16**	**40.57**
	5k	37.51	37.47
	15k	37.68	36.79
	30k	36.02	35.64
multilingual de-cs-hsb	2k	28.20	30.98
	5k	34.05	36.07
	15k	32.98	36.61
	30k	29.31	36.89

Table 8: Supervised NMT systems with BLEU scores on DevTest20.

We experimented with different methods in this shared task for both the supervised as well as unsupervised tracks. The major challenge in this task was the small amount of good quality training data as Upper Sorbian is a very low resource language. Parallel sentence extraction demands the availability of good quality data. Schwenk (2018) and Artetxe and Schwenk (2019) mention that the pre-trained LASER model seems to generalize well for minor languages and dialects including Sorbian[9], but Upper Sorbian itself is not among the languages on which the model is actually trained. As a result, LASER does not seem to give very good results for Upper Sorbian. SSNMT (Ruiter et al., 2019) however was able to learn better semantic representations and extracted quality sentence pairs from Wikipedia articles.

The lack of sufficient data for training is also one of the reasons why pre-trained language models using XLM did not give satisfactory results. The second reason is the low quality of the back-translations that were used for fine-tuning.

We have used factored machine translation where we include the *lemma* and the *PoS* of each word along with it in the corpora. Due to the lack of a proper lemmatizer for Upper Sorbian, we used UDPipe (Straka et al., 2016) for Czech as it is another language from the Slavic family. However, there are obvious linguistic differences in both the languages due to which a Czech morphological tool will not work perfectly for Upper Sorbian. This is also the reason why our *de-cs-hsb* multilingual NMT systems (Table 8) did not achieve satisfactory results. NMT models with factored source sentences improved the performances of our models by a small margin.

We have observed that a smaller BPE vocabulary is generally better for low-resource languages as expected. Here we have chosen an optimal BPE vocabulary size as choosing even smaller BPE size values would result in almost character-level segmentation. We also realise that the availability of more quality data could have improved our systems as we can first pre-train language models on good quality monolingual text data using XLM and use this as the initial model for iterative backtranslation as in the SSNMT approach. We believe that this will generate better results.

7 Conclusion and Future Work

This paper describes the UdS-DFKI submission to the shared task of unsupervised and very low resource supervised machine translation between German and Upper Sorbian at WMT20. For all our systems, we have used the standard Transformer-base architecture. We have extracted parallel data from Wikipedia dumps using SSNMT (Ruiter et al., 2019), followed by iterative back-translation for the unsupervised task. For the supervised track, we have tried to factor morphological information into our data to improve our results further. For the constrained supervised task, we achieve 40.9 BLEU for *de*(fac.)→*hsb*. We obtain BLEU scores of 10.3, 8.9, and 9.0 for the *de*→*hsb*, *hsb*→*de*, and *hsb*(fac.)→*de* translation directions respectively in the unsupervised track.

As discussed in Section 6, one approach for future work is to combine XLM pre-training along with SSNMT directly to improve system initialization. It would be interesting to explore linguistic and syntactic information from other closely-related languages to further enhance the performance of the multilingual models.

Data Selection for Unsupervised Translation of German–Upper Sorbian

{j.l.edman, a.toral.ruiz, g.j.m.van.noord}@rug.nl

Abstract

This paper describes the methods behind the systems submitted by the University of Groningen for the WMT 2020 Unsupervised Machine Translation task for German–Upper Sorbian. We investigate the usefulness of data selection in the unsupervised setting. We find that we can perform data selection using a pretrained model and show that the quality of a set of sentences or documents can have a great impact on the performance of the unsupervised neural machine translation (UNMT) system trained on it. Furthermore, we show that document-level data selection should be preferred for training the state-of-the-art UNMT model, the XLM model, when possible. Finally, we show that there is a trade-off between quality and quantity of the data used to train UNMT systems.

1 Introduction

Unsupervised Neural Machine Translation (UNMT) has recently become the dominant paradigm for unsupervised MT, with the advent of cross-lingual language model pretraining as used in the XLM model (Conneau and Lample, 2019). However, much of the existing research in UNMT assumes that the amount of data available for one language is roughly equivalent to the other. The WMT 2020 Unsupervised Machine Translation task is unique in that monolingual data is abundant for one language (German), with hundreds of millions of sentences available, and sparse for the other (Upper Sorbian), which only has around 750 thousand sentences available. With a wealth of data available on the German side, it is natural to ask: how can we best use this data? Viewing this under the lens of data selection, we break this broad question down into 3 concrete sub-questions, tailored for the unsupervised setting. They are as follows:

- How can we determine the quality of training data?
- What kinds of data selection are best for training an XLM model?
- Is quality or quantity more important when it comes to training data for UNMT?

Section 2 describes the general setup pertaining to every experiment, including datasets, data processing steps, model architecture, and training details. In Section 3, we detail our individual experiments and their corresponding results. Finally, in Section 4, we make our conclusions and discuss paths for future work.

2 Setup

For Upper Sorbian, we use the 3 monolingual datasets provided by the Sorbian Institute, the Witaj Sprachzentrum, and the web data from CIS, LMU. We also use the Upper Sorbian side of the parallel corpus from `train.hsb-de.hsb.gz`. For German, we use monolingual data from News Crawl and Common Crawl. For validation and testing, we use the data provided in `devtest.tar.gz`.

All data is tokenized and truecased using the Moses toolkit (Koehn et al., 2007). For BPE segmentation (Sennrich et al., 2016), we apply a joint segmentation for both languages. This is done by first taking a sample of the German data of the same length as the Upper Sorbian data (around 750 thousand sentences). The BPE codes are learned and applied using FastBPE.[1] After BPE is applied, we remove duplicate sentences while retaining the order of the corpora.[2]

We used the XLM model (Conneau and Lample, 2019) using the default parameters, with the excep-

[1] https://github.com/glample/fastBPE

[2] For document-level filtering, we do not remove duplicates.

Proceedings of the 5th Conference on Machine Translation (WMT), pages 1099–1103

tion of allowing for sentences of max length 200 rather than 100.[3] The language model pretraining step includes only masked language modelling, and training is limited to 24 hours. The NMT step is also limited to 24 hours, with the additional stopping criterion of no improvement on the DE→HSB validation set for 10 epochs.[4]

3 Experiments

For all of our data selection experiments, we start by training an initial model. Our initial model is trained on 10 million German sentences and all of the available Upper Sorbian sentences. The 10 million German sentences include all of the data from years 2007 and 2010, and the remaining sentences are taken from 2014.[5] Our initial model achieves BLEU scores of 17.43 and 19.05 for DE→HSB and HSB→DE respectively.

3.1 Data Selection

We apply two forms of data selection: sentence-level and document-level. As we have an abundance of German data ($\mathcal{D}$) and limited Upper Sorbian data ($\mathcal{H}$), we are only concerned with data selection for German. To select from $\mathcal{D}$, we first must score our data in terms of its potential to improve the performance of our NMT model. Drawing inspiration from Moore and Lewis (2010), our scoring function is as follows:

$$Score(s) = \frac{LM_{\mathcal{H}\rightarrow\mathcal{D}'}(s) - LM_{\mathcal{D}}(s)}{|s|}$$

In this equation, s refers to any sentence in the German data, $|s|$ to its token length, $LM_{\mathcal{X}}(s)$ to the log probability of s using a language model trained on dataset $\mathcal{X}$, and $\mathcal{H} \rightarrow \mathcal{D}'$ to the dataset obtained by translating $\mathcal{H}$ into German using the initial system. A high scoring sentence is thus a sentence that has a high probability according to the Upper Sorbian language model compared to that of the German language model.[6]

[3]The max length increase was found to perform slightly better in early testing.

[4]Both steps are limited to 24 hours as there was little to no improvement observed beyond 24 hours in preliminary tests.

[5]We choose these years because we found that the frequencies of "20XX" in the Upper Sorbian data peak at 2005, 2010, and 2014, and 2007 is the earliest News Crawl data available.

[6]The intuition behind subtracting the score of the German language model is that without it a sentence may have a high score due to it containing frequent words in general (e.g. "the") rather than words that are particularly frequent in the Upper Sorbian dataset (e.g. "Sorbia").

Selection Type	DE→HSB	HSB→DE
Sentence - Low	5.21	5.91
Sentence - Random	**16.98**	**18.45**
Sentence - High	15.08	18.05
Document - Low	9.32	8.46
Document - Random	17.03	18.19
Document - High	**17.60**	**19.23**

Table 1: BLEU scores for XLM trained on data selected with the lowest and highest sentence and document-level scores, as well as randomly selected sentences and documents.

The language model we use is KenLM (Heafield et al., 2013). We use a trigram model, with all other parameters being the default values. Since we require a portion of the German dataset to train the model, we choose N sentences randomly, with N being equal to the number of sentences in $\mathcal{H}$.[7] These sentences are not included during the selection process.

For sentence-level selection, we simply order each sentence based on score and select the sentences with the highest scores. For document-level selection, we score each document by averaging its sentence-level scores, and select the documents with the highest scores.

To answer our first research question, we show that systems trained on the highest scoring sentences and documents perform significantly better than those trained on the lowest scoring sentences and documents. For this experiment, we start with 10 million sentences from News Crawl 2015, and score each sentence and document. We then train models on the 2 million lowest and highest scoring sentences, as well as the lowest and highest scoring documents which total 2 million sentences in length. The results are shown in Table 1.

The results show a drastic improvement from using the lowest quality sentences to the highest according to our scoring function. This applies both at the sentence and document level. However only document-level filtering outperforms random selection. We speculate that this is due to a potential lack of variety in the sentence-level filtering, as it may select sentences with substantial trigram overlap, due to their similarly high score. This would be less of an issue on the document-level, since there is a smaller likelihood for two documents to have a high degree of overlap. A potential solution

[7]The choice of N follows Moore and Lewis (2010).

to this lack of variety would be to select sentences sequentially, enforcing a word overlap constraint. This would limit the number of words a sentence could share with previously selected sentences.

3.2 Document-level versus sentence-level

We see from Table 1 that document-level selection outperforms sentence-level selection. This could be for 2 reasons: either the sentences selected are higher quality on average or the language model pretraining step for the XLM model benefits more from documents than sentences. To further explain the latter reason, the pretraining step for XLM uses streams of text which can contain multiple sentences, so sentences being in order should be beneficial for training the language model. To test this, we take the document-level selected sentences and shuffle their order and train a new model. With a shuffled dataset, we obtained far lower BLEU scores of 12.84 and 16.73 for DE→HSB and HSB→DE respectively. As these BLEU scores are lower than even the scores obtained via sentence-level selection, we can conclude that the XLM model greatly benefits from sentences being in order for pretraining. However, it does appear that sentence-level selection provides higher quality sentences individually.

3.3 Quality versus quantity

With both selection methods, we can choose a threshold to determine how many sentences we should use for training our model. We start by selecting roughly 93 million sentences from News Crawl 2007-2019.[8] We chose the first 10 million sentences from each year, apart from 2008 and 2009, which only contain roughly 6.5 million sentences each. The sentences are chosen at the document-level. From the 93 million sentences combined, we use document-level selection to choose various amounts of data, varying from 1 million to 20 million sentences, and train models on each. The results are shown in Table 2.

As we can see, selecting 5 million sentences results in the highest BLEU scores. As data is either added or removed, the performance drops by around 1-2 BLEU. Given the nature of attention-based neural models, it is somewhat surprising to see that using more data is not helpful and in fact potentially harmful. Whether this is a peculiarity of the German–Upper Sorbian data or not requires further investigation.

Sentences (M)	DE→HSB	HSB→DE
1	16.01	17.14
2	15.20	16.61
5	**17.18**	**19.32**
10	16.78	18.65
20	16.09	17.75

Table 2: BLEU scores of models trained on varying amounts of document-level selected data.

Sentences (M)	DE→HSB	HSB→DE
2	17.76	19.19
5	**18.04**	**19.57**

Table 3: BLEU scores of models trained using 5 million sentences from News Crawl and various amounts of sentences from Common Crawl.

3.4 Using Common Crawl data

As a portion of the Upper Sorbian data is crawled from the web, we also perform data selection on Common Crawl. Since document boundaries are not available for Common Crawl, we can only use sentence-level selection. [9] We tested using various amounts of data in addition to the 5 million News Crawl sentences and report results in Table 3.

As we can see the system with 5 million News Crawl sentences and 5 million Common Crawl sentences performed the best. While the improvements are marginal, this may be due to a similar phenomenon as in Table 2, where too much monolingual data is not beneficial.

3.5 Iterative data selection

Since we saw improvements from one round of data selection, it would stand to reason that using a more accurate model to translate the Upper Sorbian data to German would result in potentially better data selection. As such, we use our model trained on 5 million sentences selected from News Crawl to translate the Upper Sorbian data into German, and apply the same data selection process on the roughly 93 million sentences as before.

The results on the second iteration are markedly worse, with BLEU scores of 15.9 and 17.45, on DE→HSB and HSB→DE, respectively, compared

[8] We exclude years 2007, 10, and 14 as they are used for training our initial model and thus may affect the selection.

[9] Our finding that randomly selected sentences indeed perform better was done post-hoc, which is why we use sentences selected with the highest scores.

to the original scores of 17.18 and 19.32. We suspect that this is due to the same data being used for training the NMT system and for selection, despite the data being used to train the KenLM models being different.[10]

This highlights a major downside of data selection using our methods: data cannot be used both for training a selection model and for the selection itself. The most likely reason for this is that the model will give all sentences that appear in the original training set higher scores, and documents which include the same or similar sentences will be chosen over documents that are more unique, effectively leading to an overfitting problem. This then raises a question of trade-off: is it better to use worse quality data to train the initial model and to then select from better quality data, or vice versa? Our results seem to indicate the former, but further research is required to get a definitive answer.

3.6 Further Analysis

To further analyze the data selected by the model, we look at the frequencies of words that appear in the selected data. We compare our document-filtered data from Section 3.1 with the data from the Upper Sorbian side for 10 word roots in Table 4. These word roots are selected manually as the correctly translated root is easy to verify (with Wikipedia and Wiktionary), and the translations are also one-to-one (ignoring the suffixes). We also select roots with varying frequency within the Upper Sorbian dataset.

As we can see, the high-quality document-filtered data has higher relative frequencies for the first 7 out of 10 word roots, and the lower-quality data has higher frequencies for the last 3. As the words are in order of frequency within the Upper Sorbian dataset, this indicates that the higher quality filtered data better represents the topics found in the Upper Sorbian dataset. Roots such as Sorbia- and Bautzen (a city where Sorbian is spoken) appear far more often in the higher quality data, despite being relatively uncommon in the German dataset. The last 3 words are relatively rare in the Upper Sorbian data, so it makes sense that the higher quality filtered data would have fewer occurrences of these words. Although most of the examples are related to locations, we do see that Domowin- (the root for Domowina, a non-profit organization) and Catholic- appear to show the same trends.

We also looked at the relative frequencies of the years 2000-2025 across our various models to see the effect of our filtering methods in matching the Upper Sorbian data according to year. We expect that the filtered German data with the frequency distribution most closely matching the frequency distribution of the Upper Sorbian data will have the strongest NMT performance. We show the results in Figure 1.

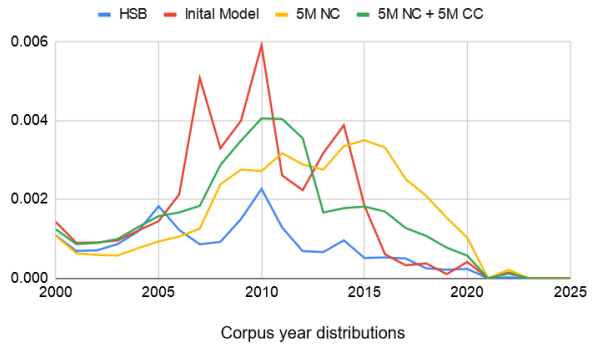

Figure 1: Relative frequencies of the years 2000-2025 within the various datasets. The frequencies are relative to the total number of sentences in that dataset.

Our initial model predictably has spikes in frequency at 2007, 2010, and 2014 as we manually chose data from these years to somewhat match the frequency of the Upper Sorbian data. Meanwhile, the 5 million document-level selected sentences from News Crawl seems to more closely match the frequencies in the Upper Sorbian data from 2000 to 2010, but has larger relative frequencies for years 2010 to 2020. We suspect that this is due to the limitation of the data available for selection, as earlier years have fewer sentences for the selection model to choose. Finally, the model using 5 million News Crawl and 5 million Common Crawl sentences has a frequency graph that most closely matches the graph of the Upper Sorbian data. The similarity of the Upper Sorbian graph to the other graphs seems to correlate with the resulting BLEU scores of the NMT model.

4 Conclusion

In the UNMT setting where one has access to a wealth of resources for one language, we investigated the feasibility of data selection. We attempt both document-level and sentence-level selection,

[10] We also saw similar performance drops when trying to include the data from years 2007, 10, and 14 in our original model trained on selected data, as these years were used to train the initial system used for selection.

Root			Count		Frequency %

Table 4: Frequencies of word roots within the Upper Sorbian (HSB), and relative frequencies of low-quality document-filtered (Doc Low) and high-quality document-filtered (Doc High) datasets. Relative frequency is based on the total frequency of each root within the 10 million sentences that the sets are selected from (i.e. the DE count column). Case is ignored when determining frequency.

finding that both methods are capable of distinguishing low quality data from high quality data, with quality in this case defined as the efficacy for training an XLM model. We found that while document-level selection chooses poorer sentences on average, the XLM model can leverage the inter-sentence information to achieve better results than when simply using the highest quality sentences. We also found that there appears to be a point where adding more monolingual data is not beneficial, but rather potentially harmful, indicating a need for data selection. Finally, we noted some potential drawbacks to using this form of data selection, particularly that data cannot be used for both initial training of the NMT model and subsequent selection. Future work could continue along many avenues, such as the effectiveness of data selection on other language pairs, or even on the Upper Sorbian side.

Abstract

We present our systems for the WMT20 Very Low Resource MT Task for translation between German and Upper Sorbian. For training our systems, we generate synthetic data by both back- and forward-translation. Additionally, we enrich the training data with German-Czech translated from Czech to Upper Sorbian by an unsupervised statistical MT system incorporating orthographically similar word pairs and transliterations of OOV words. Our best translation system between German and Sorbian is based on transfer learning from a Czech-German system and scores 12 to 13 BLEU higher than a baseline system built using the available parallel data only.

1 Introduction

In this paper, we describe systems for translation between German and Upper Sorbian developed at LMU Munich for the WMT20 shared task on very low-resource supervised MT.

Upper Sorbian is a minority language spoken by around 30,000 people in today's German state of Saxony. With such a small number of speakers, machine translation and automatic processing of Sorbian is an inherently low-resource problem without any chance that the resources available for Sorbian would ever approach the size of resources for languages spoken by millions of people. On the other hand, being a Western Slavic language related to Czech and Polish, it is possible to take advantage of relatively rich resources collected for these two languages.

The German-Sorbian systems presented in this paper are neural machine translation (NMT) systems based on the Transformer architecture (Vaswani et al., 2017). We experiment with various data preparation and augmentation techniques: back-translation (Sennrich et al., 2016b), finetuning systems trained for translation between Czech and German (Kocmi and Bojar, 2018), and data augmentation by including German-Czech parallel data with the Czech side translated to Upper Sorbian by an unsupervised system that includes an unsupervised transliteration model for guessing how to translate out-of-vocabulary Czech words to Upper Sorbian.

Our experiments show the importance of data augmentation via stochastic pre-processing and synthetic data generation. The best systems were trained by transfer-learning from a Czech-German system. However, compared to data augmentation, transfer learning from Czech-German translation only produces a minor improvement. Based on the preliminary shared task results, the presented systems scored on the 4th place among 10 competing teams in the shared task.

2 Related Work

Until recently, phrase-based approaches were believed to be more suitable for low-resource translation. Koehn and Knowles (2017) claimed that a parallel dataset of at least 10^7 tokens is required for NMT to outperform phrase-based MT. This view was also supported by the results of Artetxe et al. (2018b) and Lample et al. (2018), who showed that phrase-based approaches work well for unsupervised MT, at least in the early stages of the iterative back-translation procedure.

Recently, Sennrich and Zhang (2019) revisited the claims about data needs of supervised NMT and showed that with recent innovations in neural network and careful hyper-parameter tuning, NMT models outperform their phrase-based counterparts with training data as small as 100k tokens (15 times smaller than the data provided for this shared task).

Standard techniques for low-resource machine translation include data augmentation with rule-based substitutions (Fadaee et al., 2017), by sam-

pling synthetic noise (Wang et al., 2018; Provilkov et al., 2020), or by iterative back-translation (Hoang et al., 2018). Another class of approaches relies on transfer learning from models trained for high-resource language pairs of more or less similar languages (Zoph et al., 2016; Nguyen and Chiang, 2017; Kocmi and Bojar, 2018).

3 Data

We used several types of data to train our systems. The organizers provided authentic parallel data and Sorbian monolingual data. We also use German and Czech News Crawl data and Czech-German parallel data available in Opus (Tiedemann, 2012).

3.1 Authentic Parallel Data

The organizers of the shared task provided a parallel corpus of 60k sentences, and validation and development test data of 2k sentences each.

The basic statistics about the data are presented in Table 1. Note that the sentences are on average much shorter and therefore also likely to be structurally simpler than in the type of sentences usually used in the WMT test sets.

3.2 Monolingual Data

In total 696k monolingual Sorbian sentences were provided by the organizers. We noticed that the monolingual Sorbian data contain many OCR-related errors originating from hyphenation. We thus removed all sentences ending with a hyphen. Additionally, we merged tokens ending with a hyphen with the adjacent one if such merging results in a known Sorbian word. This filtered out 1.6k sentences and did 12k token merges.

The monolingual Sorbian data were used for training the unsupervised Czech-Sorbian translation system (see Section 4.1) and for back-translation in Sorbian-German systems.

Besides, we use 60M German and 60M Czech sentences from the NewsCrawl data provided as monolingual data for WMT shared tasks (Barrault et al., 2019). The monolingual data were used for generating synthetic training data via back- and forward-translation both for the German-Sorbian and German-Czech systems. In addition, the Czech monolingual data was used in the unsupervised Czech-Sorbian translation system as well.

3.3 German-Czech Data

For transfer learning and the creation of synthetic data, we also used German-Czech parallel data. We downloaded all available parallel datasets from the Opus project (Tiedemann, 2012), which gave us 20.8M parallel sentences, which we further filtered.

First, we filtered the parallel sentences by length. We estimated the mean and the standard deviation of the length ratio of German and Czech sentences and kept only those sentence pairs whose length ratio fitted into the interval of two times standard deviation around the mean. Then, we applied a language identifier from FastText (Grave et al., 2018) and only kept sentence pairs identified as German-Czech. The filtering lefts us with 14.7M parallel sentences.

4 Synthetic data from Czech-German

Since Upper Sorbian is related to Czech, we generate additional synthetic parallel German-Sorbian data by translating the Czech side of the German-Czech parallel data. For this, we use an unsupervised statistical MT system which includes mined Czech-Sorbian transliteration word pairs for better performance.

4.1 Unsupervised SMT

We follow the approach of Artetxe et al. (2018b) to build an Unsupervised Statistical Machine Translation (SMT) system. In the following description, we mainly focus on the steps that we changed compared to the original system and keep the description of the other steps brief.

In the first step, we build 300-dimensional monolingual n-gram embeddings for both Czech and Sor-

bian using *FastText skip-gram* (Bojanowski et al., 2017) on the above mentioned monolingual data. We restrict the vocabulary to the most frequent 200k, 400k, and 400k 1-, 2- and 3-grams, respectively. We map these embeddings to a shared bilingual space using *VecMap* (Artetxe et al., 2018a). In contrast to the original unsupervised SMT pipeline, which builds bilingual word embeddings (BWEs) without any cross-lingual signal, we use identical words occurring in both languages as the seed lexicon for the mapping. We found that the available small monolingual Sorbian corpus is not adequate to build BWEs in a fully unsupervised way. The corpora are tokenized and true-cased using *Moses* tools (Koehn et al., 2007). We note that because there are no available language rules for Sorbian, we used Czech rules for tokenization, which is reasonable because of the similarity of the two languages.

We build phrase tables for both translation directions. For each source n-gram, we take 100 candidates with the closest embeddings based on cosine similarity and additional 100 candidates with the smallest edit distance. We calculate 5 scores for each pair: phrase and lexical translation probabilities and their inverse as in (Artetxe et al., 2018b), and their normalized edit distance. For phrases, the latter is calculated by pairing each source word with the most similar target side word and taking the average edit distance of each of these pairs as the normalization constant. In addition to the phrase tables, we train language models using the monolingual corpora.

We use the validation set from the shared task (with the German side machine-translated to Czech) to tune the parameters with MERT instead of tuning on synthetic data. Finally, we run 3 iterative refinement steps.

4.2 Translating OOVs by Transliteration

Because of the small monolingual data, the Sorbian vocabulary is relatively small. To improve on this problem, we exploit the similarity of Upper Sorbian and Czech by translating Czech out-of-vocabulary (OOV) words to Upper Sorbian, using transliteration. More precisely, we transliterate Czech words from the German-Czech parallel data which were not seen by the SMT system during training, assuming that the translations of these words are missing in the Sorbian vocabulary on the target side as well. We extracted the training data for the transliteration system using a preliminary *transliteration mining* model, *filtered* the data using a preliminary transliteration model, and trained the final *transliteration model* on the filtered data.

Transliteration mining. Our transliteration mining is similar to the model by Sajjad et al. (2012). It consists of a transliteration submodel and a noise submodel.

The *transliteration submodel* is a unigram model over transliteration units (TUs) which jointly generates a source and a target language string. The English-German transliteration pair *(Gorbatchev, Gorbatschow)* could be generated as the following sequence of TUs: G:G o:o r:r b:b a:a t:t s: c:c h:h e:o v:w. We use only 1-1, 0-1, and 1-0 TUs. The probability $\mathbf{p}(\mathbf{a})$ of a sequence of TUs is the product of the unigram probabilities $p(a_i)$:

$$p(\mathbf{a}) = p(a_1, ..., a_n) = \prod_{i=1}^{n} p(a_i)$$

Probability $p_{\text{trans}}(\mathbf{s}, \mathbf{t})$ of a string pair is obtained by summing over all possible alignments $\mathbf{a}$:

$$p_{\text{trans}}(\mathbf{s}, \mathbf{t}) = \sum_{\mathbf{a} \in \text{align}(\mathbf{s}, \mathbf{t})} p(\mathbf{a})$$

The *noise submodel* independently generates a source string $\mathbf{s}$ and a target string $\mathbf{t}$ using two unigram models over the source and the target language characters, respectively. The probability of a string pair is the product of the two monolingual string probabilities:

$$p_{\text{noise}}(\mathbf{s}, \mathbf{t}) = p_{\text{src}}(\mathbf{s})\ p_{\text{tgt}}(\mathbf{t})$$

The monolingual probability of the source string (and analogously the target string) is defined as a product of letter unigram probabilities.

Sajjad et al. (2012) *interpolate* the noise model and the target model as a linear combination. Unfortunately, such a model also extracts near-transliterations which differ from a true transliteration by e.g., an inflexional affix, such as *(Gorbatchev, Gorbatschows)*.

Instead, we combine the two submodels by *concatenation*. Our model produces a word pair by (i) generating two word prefixes[1] $\mathbf{s}^p$ and $\mathbf{t}^p$ using the noise model, (ii) generating two middle parts $\mathbf{s}^m$ and $\mathbf{t}^m$ using the transliteration model, and

[1] Here, the terms *prefix* and *suffix* are not used in a linguistic sense.

(iii) generating two suffixes $\mathbf{s}^s$ and $\mathbf{t}^s$ using the noise model. The intuition is that if the most probable way to generate a pair does not use prefixes or suffixes, it is a transliteration. Here the non-transliteration pair *(Gorbatchev, Gorbatschows* might be most probably obtained by generating two empty strings as prefixes with the noise submodel, the TU sequence G:G o:o r:r b:b a:a t:t s: c:c h:h e:o v:w with the transliteration submodel, and an empty suffix and the suffix *s* with the noise model.

The probability is defined as follows:

$$p(\mathbf{s^p}, \mathbf{s^m}, \mathbf{s^s}, \mathbf{t^p}, \mathbf{t^m}, \mathbf{t^s}) = p_{\text{noise}}(\mathbf{s^p}, \mathbf{t^p}) p_{\text{trans}}(\mathbf{s^m}, \mathbf{t^m}) p_{\text{noise}}(\mathbf{s^s}, \mathbf{t^s})$$

The total probability of a word pair is obtained by summing over all possible splits:

$$p(\mathbf{s}, \mathbf{t}) = \sum_{\substack{\mathbf{s^p}, \mathbf{s^m}, \mathbf{s^s}, \mathbf{t^p}, \mathbf{t^m}, \mathbf{t^s} \\ \in \text{split}(\mathbf{s}, \mathbf{t})}} p(\mathbf{s^p}, \mathbf{s^m}, \mathbf{s^s}, \mathbf{t^p}, \mathbf{t^m}, \mathbf{t^s})$$

The parameters of the transliteration submodel are trained using the EM algorithm on the list of transliteration candidates. The parameters of the monolingual models are estimated directly from the data and kept fixed during training. After the EM training, we compute for each candidate pair, the most probable split of the two words into prefix/middle/suffix, and the most probable alignment of the two middle parts using the Viterbi algorithm. If all prefixes and suffixes are empty, the candidate pair is extracted as a probable transliteration.

We run the transliteration mining on lower-cased data and consider all possible word pairs with a reasonable edit distance. The mining process returns the extracted transliteration candidates and their most probable TU sequence, respectively.

Transliteration filtering. The mining process only relies on the unigram probabilities, which is often suboptimal. Therefore, we add a filtering step that scores each transliteration pair using an n-gram transliteration model and eliminates pairs with a low score.

We train a Kneser-Ney-smoothed trigram transliteration model on the TU sequences of the transliterations extracted using the transliteration mining model.

For each extracted transliteration pair, we compute negative log probabilities:

- L_1 of the corresponding TU sequence;
- L_2 of the best source-to-target transliteration; and
- L_3 of the best target-to-source transliteration.

We filter out a word pair if $L_2 - L_1 + L_3 - L_1 > 10$. Note that all three probabilities are joint probabilities and that the same transliteration model can be used in both directions.

Unsupervised SMT	12.0
+ edit distance	13.3
+ transliteration	13.8

Table 2: BLEU scores of the Czech-Sorbian system with gradually added techniques measured on the Upper Sorbian-German test set where the German side has been machine-translated to Czech.

Transliteration Generation. We train the final transliteration model on the TU sequences of the filtered transliteration pairs and use the model to generate Sorbian transliterations for Czech OOV words. We lowercase the Czech words before transliteration and transfer the casing from the original Czech words to their Sorbian transliterations.

Using the model, we generate transliterations for Czech words not seen by the unsupervised SMT system during training, i.e., we take all the words from the Czech side of the parallel data which are not present in the used Czech monolingual corpus. To add these word pairs to the SMT system, we consider them as a parallel corpus and concatenate it to the synthetic parallel data created in the iterative refinement steps and also update the language models. We run two additional refinement steps on top of the three mentioned in 4.1. Finally, we create the synthetic German-Sorbian data by translating the Czech side of the German-Czech data and feed it to our final NMT system, as described below.

Table 2 shows the translation quality of the unsupervised SMT system. The basic setup relies only on BWEs to build the initial phrase tables. Next, we add edit distance information, and finally, we use the mined transliteration pairs as well. However, note that the BLEU scores are very approximate because the source side of the test is machine-translated.

5 Experimental Setup

For the translation between German and Sorbian, we experimented with NMT models based on

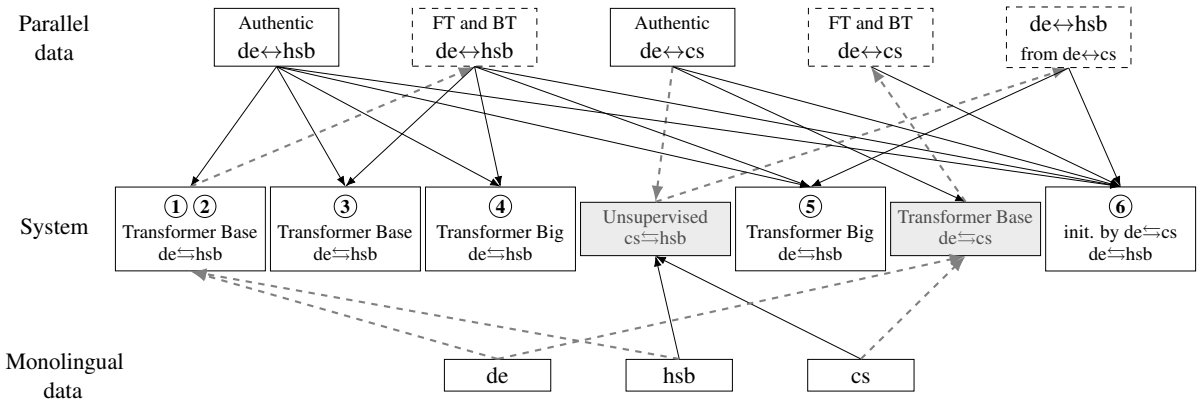

Figure 1: Overview of datasets and systems that were used to generate synthetic data. Solid arrows denote training a system, dashed gray arrows denote using the model for data generation. Synthetic datasets have dashed boxes.

Transformers (Vaswani et al., 2017). We followed known best practices for architecture and optimization choices. In our experiments, we mostly focus on data engineering.

5.1 Model Architecture and Optimization

We use the Transformer architecture (Vaswani et al., 2017) as implemented in Marian (Junczys-Dowmunt et al., 2018). For the initial experiments, we used the Base architecture (6 layers, hidden state of size 512, 8 attention heads, feed-forward layer 1024), and Big for the later experiments (12 layers, hidden state 1024, 16 attention heads, feed-forward layer 4096). We follow the default standard learning rate schedule proposed by Vaswani et al. (2017) with learning rate $3 \cdot 10^{-4}$. We use 16k warm-up steps for the Base architecture and 32k warm-up steps for the Big architecture.

The Base architecture is used for the initial systems which generate synthetic data via backward- and forward-translation. We use the Big architecture for the rest of the systems.

5.2 Training Data Preparation

An overview of the data generation and system training steps is provided in Figure 1.

We use a common BPE-based vocabulary (Sennrich et al., 2016c) for all systems which allows us to better ensemble our systems. Instead of proper tokenization, we use the pre-tokenization heuristic from SentencePiece (Kudo and Richardson, 2018) as implemented in YouTokenToMe.[2] The BPE vocabulary consists of 16k merges and was fit using the authentic parallel training data only.

[2]https://github.com/VKCOM/YouTokenToMe

We apply BPE-dropout (Provilkov et al., 2020) of 0.1 on both the source and the target side of the data. We oversample the monolingual data 1000 times and with different segmentations (Model 2). We hypothesize that in the very low-resource setup, the BPE dropout serves more as a data-augmentation technique than as regularization.

Due to hardware limitations, we limit the data mixes for training the Big architectures to 180M parallel sentences. One third of the data mix consists of oversampled authentic parallel data. In one set of experiments (Models 3, 4), the rest of the data consists of synthetic data: an equal number of samples of forward- and back-translation (which means that the monolingual Sorbian data is oversampled approximately 80×). In another set of experiments (Model 5), we additionally sample data from the machine-translated Czech-German data set where the Czech part has been automatically translated to Upper Sorbian. Following Caswell et al. (2019), we tag the synthetic data, having a separate tag for each of the synthetic data types.

Further, we experiment with finetuning models originally trained for translation between Czech and German. The data for the parent models is prepared using the same protocol as for Model 4. Following Kocmi and Bojar (2018), we train the parent model until convergence and continue training with the German-Sorbian data. Based on preliminary results, we use the data mix for Model 4 for the German-to-Sorbian translation direction and the data mix for Model 5 for translating from Sorbian into German.

	Model	hsb→de		de→hsb	
1	Transformer Base, parallel only	43.4	.695	45.6	.702

Table 3: BLEU scores and chrF scores (in small font) on development test data for Sorbian-to-German (hsb→de) and German-to-Sorbian (de→hsb) translations.

5.3 Model Ensembling

Following Sennrich et al. (2016a), we also experiment with ensembling several systems and combining systems trained in the left-to-right and right-to-left direction.

We trained four models from random initialization and three models by transferring from Czech-German translation. Note that the transferred models were initialized by the same model and only differed in the order of the training data.

Further, we trained two models in the right-to-left direction, starting from random initialization.

6 Results

The quantitative results in terms of BLEU score (Papineni et al., 2002) and ChrF (Popović, 2017) score are presented in Table 3. The results were measured using SacreBLEU.[3]

The Base architecture trained using the parallel data only (Model 1) reaches a surprisingly high BLEU score, which is probably due to the quality of the manually curated training data, domain closeness of the train and test data, and relatively simple sentences both in the train and test sets.

The data augmentation using BPE-dropout (Model 2) seems to have a substantial effect on the translation quality, improving the translation by 6–7 BLEU points. This is a much larger effect than Provilkov et al. (2020) reported. However, they also observed a larger positive effect on smaller datasets. Unlike Sennrich and Zhang (2019), we did not find any benefits of using a small BPE-based vocabulary or tuning learning rate. However, the positive effect of the small vocabulary might be partially emulated by the BPE dropout.

Adding the back- and forward-translated data in the training data improved the translation quality only slightly (Model 3). A large positive effect can be achieved by switching to the Big architecture (Model 4). Adding the synthetic data generated from Czech-German parallel data improve only the Sorbian-to-German translation direction (Model 5), presumably because the quality of the synthetic Sorbian side of the corpus is too low to be used as a target side.

Transfer learning from German-Czech models further improves the translation quality by approximately 1 BLEU point. These are thus the best single models we have developed and our contrastive submission to the shared task.

Additional improvements were reached by model ensembling. Ensembling both the model trained from random initialization and transfer learning models improves the translation by approx. 1 BLEU point. Ensembling these two model types together further improves the translation quality by around half BLEU point.

The model generating the translation right-to-left reach translation quality that is comparable to the left-to-right models. However, rescoring of the n-best lists generated by left-to-right ensembles by the right-to-left models improves the translation quality only negligibly. The rescored ensemble was our primary submission to the shared task.

7 Conclusions

We presented NMT systems for translation between German and Upper Sorbian. Due to the domain closeness and relative simplicity of the test data, we were able to achieve BLEU scores over 50 using the parallel data only. The crucial component was the use of BPE-dropout for both the source and target side.

Further translation quality improvements were achieved by generating synthetic training data by back- and forward-translation. Additionally, we generated synthetic data by machine-translating the Czech side of a parallel German-Czech corpus. For that, we built an unsupervised SMT system that additionally utilizes an unsupervised transliteration system for the translation of OOV tokens.

Our best single system is based on transfer learning, i.e., initializing the model by a Czech-German system, reaching 1–2 higher BLEU scores compared to systems based on Sorbian and German data only. Further minor improvements were achieved by model ensembling and right-to-left rescoring.

Abstract

We describe the National Research Council of Canada (NRC) neural machine translation systems for the German–Upper Sorbian supervised track of the 2020 shared task on Unsupervised MT and Very Low Resource Supervised MT. Our models are ensembles of Transformer models, built using combinations of BPE-dropout, lexical modifications, and backtranslation.

1 Introduction

We describe the National Research Council of Canada (NRC) neural machine translation systems for the shared task on Unsupervised MT and Very Low Resource Supervised MT. We participated in the supervised track of the low resource task, building Upper Sorbian–German neural machine translation (NMT) systems in both translation directions. Upper Sorbian is a minority language spoken in Germany. We built baseline systems (standard Transformer (Vaswani et al., 2017) with a byte-pair encoding vocabulary (BPE; Sennrich et al., 2016b)) trained on all available parallel data (60,000 lines), which resulted in unusually high BLEU scores for a language pair with such limited data.

In order to improve upon this baseline, we used transfer learning with modifications to the training lexicon. We did this in two ways: by experimenting with the application of BPE-dropout (Provilkov et al., 2020) to the transfer learning setting (Section 2.3), and by modifying Czech data used for training parent systems with word and character replacements in order to make it more "Upper Sorbian-like" (Section 2.4).

Our final systems were ensembles of systems built using transfer learning and these two approaches to lexicon modification, along with iterative backtranslation.

2 Approaches

2.1 General System Notes

In both translation directions, our final systems consist of ensembles of multiple systems, built using transfer learning (Section 2.2), BPE-Dropout (Section 2.3), alternative preprocessing of Czech data (Section 2.4), and backtranslation (Section 2.5). We describe these approaches and related work in the following sections, providing implementation details for reproducibility in Sections 3, 4 and 5.

2.2 Transfer Learning

Zoph et al. (2016) proposed a transfer learning approach for neural machine translation, using language pairs with larger amounts of data to pre-train a parent system, followed by finetuning a child system on the language pair of interest. Nguyen and Chiang (2017) expand on that, showing improved performance using BPE and shared vocabularies between the parent and child. We follow this approach: we build disjoint source and target BPE models and vocabularies, with one vocabulary for German (DE) and one for the combination of Czech (CS) and Upper Sorbian (HSB); see Section 4.

We chose to use Czech–German data as the parent language pair due to the task suggestions, relative abundance of data, and the close relationship between Czech and Upper Sorbian (cf. Lin et al., 2019; Kocmi and Bojar, 2018). While Czech and Upper Sorbian cognates are often not identical at the character level (Table 1), there is a high level of character-level overlap; trying to take advantage of that overlap without assuming complete character-level identity is a motivation for the explorations in subsequent sections (Section 2.3, Section 2.4). Another relatively high-resource language related to Upper Sorbian is Polish, but while the Czech and Upper Sorbian orthographies are fairly similar, mostly using the same characters for the same

Proceedings of the 5th Conference on Machine Translation (WMT), pages 1112–1122

sounds (with a few notable exceptions), Polish orthography is more distinct. This, combined with the lack of a direct Polish–German parallel dataset in the constrained condition, led us to choose Czech as our transfer language for these experiments.

Czech	Upper Sorbian
analyzovat	analyzować
donesl	donjesł
externích	eksternych
hospodářská	hospodarsce
kreativní	kreatiwne
okres	wokrjes
potom	potym
projekt	projekt
sémantická	semantisku
velkým	wulkim

Table 1: A sample of probable Czech–Upper Sorbian cognates and shared loanwords, mined from the Czech–German and German–Upper Sorbian parallel corpora and filtered by Levenshtein distance.

Other work on transfer learning for low-resource machine translation includes multilingual seed models (Neubig and Hu, 2018), dynamically adding to the vocabulary when adding languages (Lakew et al., 2018), and using a hierarchical architecture to use multiple language pairs (Luo et al., 2019).

2.3 BPE-Dropout

We apply the recently-proposed approach of performing BPE-dropout (Provilkov et al., 2020), which takes an existing BPE model and randomly drops some merges at each merge step when applying the model to text. The goal of this, beside leading to more robust subword representations in general, is to produce subword representations that are more likely to overlap between the pretraining (Czech–German) and finetuning (Upper Sorbian–German) stages. We hypothesized that, in the same way that BPE-Dropout leads to robustness against accidental spelling errors and variant spellings (Provilkov et al., 2020), it could likewise lead to robustness to the kind of spelling variations we see between two related languages.

For example, consider the putative Czech–Upper Sorbian cognates and shared loanwords presented in Table 1. Sometimes a fixed BPE segmentation happens to separate shared characters into shared subwords (e.g. CS `analy@@ z@@ ovat` vs. HSB `analy@@ z@@ ować`), such that the presence of the former during pre-training can initialize at least some of the subwords that the model will later see in Upper Sorbian. However, other times the character-level differences lead to segmentations where no subwords are shared (e.g. CS `hospodář@@ ská` vs. HSB `hospodar@@ sce` or `potom` vs. HSB `po@@ tym`). Considering a wider variety of segmentations would, we hypothesized, mean that Upper Sorbian subwords would have more chance of being initialized during Czech pre-training (see Appendix C).

Rather than modifying the NMT system itself to reapply BPE-dropout during training, we treated BPE-dropout as a preprocessing step. Additionally, we experimented with BPE-dropout in the context of transfer learning, examining the effects of using source-side, both-sides, or no dropout in both parent and child systems.

2.4 Pseudo-Sorbian

For the Upper Sorbian–German direction, we also experimented with two techniques for modifying the Czech–German parallel data so that the Czech side is more like Upper Sorbian. In particular, we concentrated on modification methods that require neither large amounts of data, nor in-depth knowledge of the historical relationships between the languages, since both of these are often lacking for the lower-resourced language.

We considered two variations of this idea:

- *word-level* modification, in which some frequent Czech words (e.g. prepositions) are replaced by likely Upper Sorbian equivalents, and
- *character-level* modification, where we attempt to convert Czech words at the character level to forms that may more closely resemble Upper Sorbian words.

Note that in neither case do we know what particular conversions are *correct*; we ourselves do not know enough about historical Western Slavic to predict the actual Upper Sorbian cognates of Czech words. Rather, we took inspiration from stochastic segmentation methods like BPE-Dropout (Provilkov et al., 2020) and SentencePiece (Kudo and Richardson, 2018): when we have an idea of the *possible* solutions to the segmentation problem but do not know which one is the *correct* one, we can sample randomly from the possible segmentations as a sort of regularization, with the

goal of discouraging the model from relying too heavily on a single segmentation scheme and giving it some exposure to a variety of possible segmentations. Whereas BPE-dropout and SentencePiece focus on possible segmentations of the word, our pseudo-Sorbian experiments focus on possible word- and character-level replacements. The goal was to discourage the parent Czech–German model from relying too heavily on regularities in Czech (e.g. the presence of particular frequent words, the presence of particular Czech character *n*-grams) and perhaps also gain some prior exposure to Upper Sorbian words and characters that will occur in the genuine Upper Sorbian data; we can also think of this as a form of low-resource data augmentation (Fadaee et al., 2017; Wang et al., 2018). See Appendix C for an analysis of increased subword overlap between pseudo-Sorbian and test data, as compared to BPE-dropout and the baseline approach.

2.4.1 Word-level pseudo-Sorbian

To generate the word-level pseudo-Sorbian, we ran `fast_align` (Dyer et al., 2013) on the Czech–German and German–Upper Sorbian parallel corpora, and took the product of the resulting word correspondences, to generate candidate Czech-Upper Sorbian word correspondences. As this process produces many unlikely correspondences, particularly for words that occur only a few times in the corpora, we filtered this list so that any Czech–German word correspondence that occurred fewer than 500 times in the aligned corpus was ineligible, and likewise any German–Upper Sorbian correspondence that occurred fewer than 50 times. We then used these correspondences to randomly replace 10% of eligible Czech words in the Czech-German corpus with one of their putative equivalents in Upper Sorbian. The result is a language that is *mostly* still Czech, but in which some high-frequency words (especially prepositions) are Upper Sorbian.

2.4.2 Character-level pseudo-Sorbian

To generate the character-level pseudo-Sorbian, we began with the same list of putative Czech-Upper Sorbian word correspondences, calculated the Levenshtein distances (normalized by length) between them, and filtered out pairs that exceeded 0.5 distance. This gave a list of words that were likely cognates, from which we hand-selected a development set of about 200; a sample of these is seen in Table 1. Using this set to identify character-level correspondences (e.g. CS `v` to HSB `w`, CS `d` to HSB `dź` before front vowels, etc.), we wrote a program to randomly replace the appropriate Czech character sequences with possible correspondences in Upper Sorbian. Again, as Czech-Upper Sorbian correspondences are not entirely predictable (CS `e` might happen to correspond, in a particular cognate, to HSB `e` or `ej` or `i` or `a` or `o`, etc.), we cannot expect that any given result is correct Upper Sorbian. Rather, we can think of this process as attempting to train a system that can respond to inputs from a variety of possible (but not necessarily actual) Western Slavic languages, rather than just a system that can respond to precisely-spelled Czech and only Czech.

2.4.3 Combined pseudo-Sorbian

In initial testing, we determined that a combination of word-level and character-level modification performed best; we ran each process on the Czech–German corpus separately, then concatenated the resulting corpora and trained a parent model on it. Due to time constraints we did not run the full set of ablation experiments. Subsequent finetuning on genuine Upper Sorbian–German data proceeded as normal, without any modification.

For all pseudo-Sorbian systems, we used the BPE vocabulary trained on the original Czech and Upper Sorbian data, rather than the modified data, so that systems trained on pseudo-Sorbian data could still be ensembled with systems trained only on the original data (Section 2.6).

2.5 Backtranslation

We used backtranslation (Sennrich et al., 2016a) to incorporate monolingual German and Upper Sorbian data into training. We backtranslated all Upper Sorbian monolingual data (after filtering as described in Section 3). We backtranslated the German monolingual news-commentary data and 1.2M randomly sampled lines of 2019 German news.

We experiment with iterative backtranslation: backtranslating data using systems without backtranslation, and then using the new systems built using the backtranslated text to perform a second iteration of backtranslation (Hoang et al., 2018; Niu et al., 2018; Zhang et al., 2018). Like Caswell et al. (2019), we use source-side tags at the start of backtranslated sentences to indicate to the models which sentences are the product of backtranslation.

2.6 Ensembling

Our final systems are ensembles of several systems. Because all systems used the same vocabulary sets and same model sizes, we could decode using Sockeye's (Hieber et al., 2018) default ensembling mechanism.

3 Data

We used all provided parallel German–Upper Sorbian data and all monolingual Upper Sorbian data (after filtering), along with German–Czech parallel data from Open Subtitles (Lison and Tiedemann, 2016),[1] DGT (Tiedemann, 2012; Steinberger et al., 2012), JW300 (Agić and Vulić, 2019), Europarl v10 (Koehn, 2005), News-Commentary v15, and WMT-News[2] for building the BPE vocabularies. The monolingual Upper Sorbian Web and Witaj datasets[3] were filtered to remove lines containing characters that had not been observed in the Upper Sorbian parallel data or in the Czech data; this removed sentences that contained text in other scripts and other languages. The Czech–German data was used for training parent models, while monolingual German and Upper Sorbian were used (along with parallel German–Upper Sorbian data) for training child models. A table of data sizes and how they were used is shown in Appendix A.

4 Preprocessing

We build BPE vocabularies of size 2k, 5k, 10k, 15k, and 20k using `subword-nmt`[4] (Sennrich et al., 2016b). After building the vocabulary, we add a set of 25 generic tags, plus a special backtranslation tag "<BT>", which we use in future experiments for indicating when training data has been backtranslated (Caswell et al., 2019). We also add all Moses and Sockeye special tags (ampersand, <unk> etc.) to a glossary file used for applying BPE, which prevents them from being segmented.

Because there is so much more Czech data than Upper Sorbian data, we duplicate the in-domain parallel hsb-de data and the monolingual HSB data 25 times when training BPE in order to make sure that HSB data is adequately represented (and not overwhelmed by Czech data) in training the encoding. After training BPE, we extract (and fix for the remainder of our experiments) a single DE vocabulary and a single HSB-CS vocabulary, covering all the relevant data used to train BPE for that language pair.

We ran BPE-dropout with a rate of 0.1 over the training data 5 times using the same BPE merge operations, vocabularies and glossaries as before, concatenating these variants to form an extended training set.

		Child Dropout		
		None	Source	Both
Parent Dropout	None	54.6	54.5	54.3
	Source	55.0	**55.5**	54.2
	Both	54.9	**55.5**	55.0

Table 2: Comparison of BPE-dropout use in both parent and child systems for 10k vocabulary DE-HSB translation (measured on devel_test set), without backtranslation. All parent systems were trained on the German-Czech data, while child systems trained on the parallel DE-HSB data. *None* involves no BPE-dropout, *source* applies BPE-dropout to the source side only, and *both* applies it to both the source and the target.

5 Software and Systems

We used Sockeye's (Hieber et al., 2018) implementation of Transformer (Vaswani et al., 2017) with 6 layers, 8 attention heads, network size of 512 units, and feedforward size of 2048 units. We have changed the default gradient clipping type to absolute, used the whole validation set during validation, an initial learning rate of 0.0001, batches of ∼8192 tokens/words, maximum sentence length of 200 tokens, optimizing for BLEU. Parent systems used checkpoint intervals of 2500 and 4000. Child system checkpoint intervals varied from 65 to 4000 to balance frequent checkpointing with efficiency. Decoding was performed with beam size 5.

6 Results and Discussion

6.1 BPE-Dropout in Transfer Learning

Provilkov et al. (2020) examine BPE-dropout when building translation systems for individual language pairs. Here we apply it in a transfer learning setting, raising the question of whether BPE-dropout should be applied to the parent system, the child system, or both, as well as the question of using source-side BPE-dropout or both source- and target-side BPE-dropout.

[1] http://www.opensubtitles.com
[2] http://www.statmt.org/wmt20/translation-task.html
[3] http://www.statmt.org/wmt20/unsup_and_very_low_res/
[4] https://github.com/rsennrich/subword-nmt

Our results for this are somewhat mixed, owing in part to the relatively small BLEU gains produced by BPE-dropout (as compared to backtranslation). In Table 2 we show BLEU scores for German–Upper Sorbian translation with a 10k vocabulary and no backtranslation. The most promising systems in that experiment are those with source-side BPE-dropout in the child system, with either both side or source-side dropout in the parent. In the 20k vocabulary DE-HSB setting with second iteration backtranslation, we saw a similar effect, with source BPE-dropout for both parent and child having a BLEU score of 58.4 on devel_test, +1.1 above the second-best system (no BPE-dropout in parent or child). Results in the other translation direction were more ambiguous, leaving room for future analysis of BPE-dropout in the transfer learning setting.

As a result of these experiments, many of the systems we used in our final ensembles were trained with source-side BPE-dropout, though when it appeared promising we also ensembled with systems without BPE-dropout.

6.2 Iterative Backtranslation

We performed two rounds of backtranslation of Upper Sorbian monolingual data and German monolingual data described in Section 2.5. The first round (BT1) used our strongest system without backtranslation, while the second round (BT2) used our strongest system including backtranslated data from the first round. We ran experiments sweeping BPE vocabulary sizes and backtranslated corpora; for German news we experimented 300k and 600k subsets as well as the full 1.2M line random subselection. In all experiments the 60k sentence-pair parallel HSB-DE corpus was replicated a number of times to approximately match the included backtranslated data in number of lines.

The second round of backtranslation of the Upper Sorbian monolingual data improved the BLEU score by 0.7 BLEU points for the best configuration, with the vocabulary size of the best configuration increasing to 20k from 15k. However, the second round of backtranslation of the German monolingual data did not improve the subsequent HSB-DE systems, instead showing a drop of 0.1 BLEU points; our final system (Section 6.5) uses a mix of systems trained using BT1 and BT2. For full details of the systems used for backtranslation, see Appendix B.

System	DE-HSB	HSB-DE
Baseline	44.2	44.1
Base. + BPE-Dr.	44.4	44.7
Base. + BT2	54.9	54.7
Base. + BT2 + BPE-Dr.	56.1	55.0
Child	54.7	53.4
Child + BPE-Dr.	55.5	54.1
Child + BT2	57.7	56.5
Child + BT2 + BPE-Dr.	58.4	56.8
Final Submitted Systems	59.4	58.9

Table 3: Ablation experiments showing performance of baseline systems, BPE-dropout, backtranslation, transfer learning, and their combination. All systems shown here do not use pseudo-Sorbian. DE-HSB systems here have a 20k vocabulary, while HSB-DE have a 10k vocabulary. BLEU score is reported on devel_test set. The final line shows the submitted primary systems and their performance on devel_test.

Generating multiple translation for backtranslation (i.e. multiple source sentences for each authentic target sentence) is known to improve translation quality (Imamura et al., 2018; Imamura and Sumita, 2018); all of the systems we have described here used a single backtranslation per target sentence. After the submission of our final systems, we experimented with backtranslation using *n*-best translations of the monolingual text. In both directions, we found that building student systems using the 10-best backtranslation list generated with sampling from the softmax's top-10 vocabulary (rather than taking the max), but without BPE-dropout, produced improvements of around 0.2-0.8 BLEU.[5] The resulting systems had comparable BLEU scores to the systems trained with single variant backtranslation and BPE-dropout; we leave as future work an examination of the result of combining multiple backtranslations with BPE-dropout.

6.3 Ablation

Here we first discuss the impact of our non-pseudo-Sorbian approaches: BPE-dropout, backtranslation, and transfer learning, showing how each contributed to the final systems used for ensembling.

Table 3 shows ablation experiments for DE-HSB (20k vocabulary) and HSB-DE (10k vocabulary).[6] In the first four lines, we consider training a system without transfer learning, starting from a base-

[5] Authentic bitext was upsampled to keep the ratio identical to our prior experiments.

[6] Smaller vocabulary sizes perform better on the baseline experiments, but the trends remain the same, so we show results for our final vocabulary sizes.

line built using only the parallel Upper Sorbian–German data. Despite the small data size, and perhaps due to the close match between training and test data, this baseline has high BLEU scores on the devel_test set: 44.2 (DE-HSB) and 44.1 (HSB-DE). Adding BPE-dropout to this setting (with 5 runs of the algorithm) results in a modest improvement (+0.2 BLEU for DE-HSB and +0.6 BLEU for DE-HSB). If we instead add backtranslated data (translated in our second iteration of backtranslation), we see a much larger jump of +10.7 and +10.6 BLEU respectively over the baselines; note that this also represents a huge increase in available data for training. Combining the two approaches adds an additional +1.2 and 0.3 BLEU, respectively.

In fact, these systems outperform both a parent-child baseline and a parent-child system with BPE-dropout, highlighting the importance of incorporating additional target-side monolingual data in the low-resource setting. Once we combine backtranslation we see a moderate improvement over the child systems with BPE-dropout (+2.6 and +2.4 BLEU, respectively). Again, combining BPE-dropout and backtranslation still produces more improvement, as does eventual ensembling.

Due to time constraints, we did not run a full ablation study of word, character and combined pseudo-Sorbian. Our initial results (run with an earlier version of character pseudo-Sorbian, and a differently extracted BPE vocabulary) found for the HSB-DE direction that word pseudo-Sorbian slightly outperformed (on the order of 0.5 BLEU) character pseudo-Sorbian for 10k vocabulary, but was comparable for 2k and 5k vocabulary sizes; these results are given in Appendix C. The combination of the two had slightly higher scores across those three vocabulary sizes (ranging from +0.1 to +0.6 BLEU) than either of the two individual approaches, so we used the combination for the remaining experiments.

6.4 Final German–Upper Sorbian System

System	BLEU
1. Child + BT2	57.7
2. Child + Src. BPE-Dr. + BT2	58.4
3. Pseudo-Sorbian + Child + BT2	57.8
4. Pseudo. + Child + Src. BPE-Dr. + BT2	58.2
Ensemble	**59.4**

Table 4: Primary German–Upper Sorbian ensemble submission BLEU score on devel_test, with scores of each of its individual component systems. The system numbers correspond to the list in Section 6.4.

Our final German–Upper Sorbian system is an ensemble of four systems, with vocabulary size of 20k merges. All child models ensembled were trained on second iteration backtranslated monolingual HSB data (all available, filtered) and 12 replications of the de–hsb parallel text, with backtranslation tags.

1. Child without BPE-dropout, de–cs parent without BPE-dropout.
2. Child with source side BPE-dropout, de–cs parent with source side BPE-dropout
3. Child without BPE-dropout, pseudo-hsb–de parent without BPE-dropout.
4. Child with source side BPE-dropout, pseudo-hsb–de parent with source side BPE-dropout

The system scores on devel_test are shown in Table 4. The best scoring individual systems were transfer learning systems with source-side BPE-dropout, with the one using pseudo-Sorbian falling slightly behind the non-pseudo-Sorbian by 0.2 BLEU points. Without BPE-dropout, the best pseudo-Sorbian system shown here outperforms its corresponding non-pseudo-Sorbian system by approximately 0.1 BLEU. On the test set, this system had scores of (as computed by the Matrix submission) 57.3 BLEU-cased, TER (Snover et al., 2006) of 0.3, BEER 2.0 (Stanojević and Sima'an, 2014) of 0.754, and CharacTER (Wang et al., 2016) of 0.255. This was 3.4 BLEU-cased behind the best-scoring system (SJTU-NICT), but within 0.6 BLEU of the second- and third-highest scoring systems (University of Helsinki); it was also tied with the third-highest scoring system (University of Helsinki) in terms of CharactTER.

6.5 Final Upper Sorbian–German System

System	BLEU
1. Child + BPE-Dr. + BT1	57.2
2. Child + BT2	57.1
3. Pseudo. + Child + BT1	57.2
4. Pseudo. + Child + BPE-dr. + BT1	57.1
5. Pseudo. + Child + BT2	57.1
Ensemble	**58.9**

Table 5: Primary Upper Sorbian–German ensemble submission BLEU score on devel_test, with scores of each of its individual component systems. The numbers correspond to the list in Section 6.5.

The final Upper Sorbian–German system is an ensemble of systems with a BPE vocabulary of 10k merges.

1. Child with source side BPE-dropout, 20 times hsb–de data, 1.2M lines of first iteration backtranslated news data; cs–de parent with source side BPE-dropout
2. Child without BPE-dropout, 25 times hsb–de data, news commentary (NC) and 1.2M lines of news second iteration backtranslated;[7] cs-de parent without BPE-dropout
3. Child without BPE-dropout, 25 times hsb–de data, NC and 1.2M lines of news first iteration backtranslated; pseudo-hsb–de parent without BPE-dropout
4. Child with source side BPE-dropout, 25 times hsb–de data, NC and 1.2M lines of news first iteration backtranslated; pseudo-hsb–de parent with source side BPE-dropout
5. Child without BPE-dropout, 20 times hsb–de data and 1.2M lines of second iteration backtranslated news data; pseudo-hsb–de parent without BPE-dropout

Table 5 shows that the five systems combined were very comparable in BLEU scores (57.1 and 57.2), but their ensembled BLEU score showed an improvement of $\geq$1.7 BLEU over each individual score. The final ensemble had a BLEU-cased score of 58.9 on the test data (calculated by the Matrix submission systems), a TER of 0.29, a BEER 2.0 of 0.579, and a CharacTER score of 0.268. This represented a -0.7 BLEU-cased difference off of the best system (University of Helsinki), but only a -0.001 CharactTER difference.

6.6 Discussion

We experimented with a variety of ensembles, and found that our strongest ensembles were those that included both the pseudo-Sorbian systems and those built without pseudo-Sorbian. In initial experiments with Upper Sorbian-German systems, with vocabulary size 5k, we found that adding pseudo-Sorbian systems to ensembles produced improvements even if the pseudo-Sorbian system did not have quite as high of a BLEU score as the systems built without it. For example, combining the top three systems without pseudo-Sorbian (BLEU scores of 57.3, 57.2, and 57.0, respectively) or the top two of those systems resulted in ensemble system BLEU scores of 57.9. Replacing the third-best system with a pseudo-Sorbian system with a BLEU score of 56.6 resulted in an improved ensemble BLEU score of 58.5. Diverse ensembles (e.g., different architectures or runs) are known to outperform less diverse ensembles (e.g., ensembles of checkpoints) for neural machine translation (Farajian et al., 2016; Denkowski and Neubig, 2017; Liu et al., 2018). While diversity of models for ensembling is usually discussed in terms of model architecture or seeding of multiple runs, we could argue that the use of lexically modified training data could constitute another form of model diversity, contributing to a stronger ensembled model.

For baseline systems trained only on the parallel data, smaller vocabulary sizes performed best, as expected (given only 60,000 lines of text, large vocabulary sizes may contain many tokens that are only observed a small number of times). As we added transfer learning, backtranslation, and eventually ensembling, the best systems were those with slightly larger vocabulary sizes. In the Upper Sorbian–German translation direction, some of our best performing systems that did not use pseudo-Sorbian were found with a 5k vocabulary size, while 10k was generally better for the pseudo-Sorbian systems. We tried ensembles with both 5k and 10k that included pseudo-Sorbian and non-pseudo-Sorbian systems, and found the best results with 10k.

7 Conclusions

In this work, we demonstrated that transfer learning, BPE-dropout, and backtranslation all provide improvements for this low-resource setting. Our experiments on lexical modifications, building pseudo-Sorbian text for training parent models, performed approximately on-par with standard transfer learning approaches, and could be trivially combined with BPE-dropout. While the lexical modification approach did not outperform the standard transfer learning setup, we found that it still improved ensembles, possibly due to the increase in system diversity.

Acknowledgments

We thank the reviewers for their comments and suggestions. We thank Yunli Wang, Chi-kiu Lo, Sowmya Vajjala, and Huda Khayrallah for discussion and feedback.

[7] This version of the second iteration backtranslation differs slightly from that used in the remainder of the experiments, in that UNKs (tokens representing unknown words) were not filtered out.

A Data

Table 6 shows the data sizes, including the size after filtering for the monolingual Upper Sorbian data, as well as how each dataset was used for BPE training and vocabulary extraction, parent training, and/or child training.

B Backtranslation Details

The configurations used to backtranslate the first round were:

- For monolingual Upper Sorbian, the HSB–DE child system with 5k vocabulary size and both source and target side BPE-dropout for both the HSB–DE system and its CS–DE parent (53.4 BLEU on devel_test)
- For monolingual German, the DE–HSB child with 10k vocabulary size and both source and target side BPE-dropout for both the DE–HSB system and its DE–CS parent (55.0 BLEU on devel_test).

The following configurations were used to backtranslate the second round:

- For monolingual Upper Sorbian, the HSB–DE child system with 5k vocabulary size and source side BPE-dropout for both the HSB–DE system and its CS–DE parent; 25 times hsb–de data, DE news commentary and 1.2M lines of DE news backtranslated (57.25 BLEU on devel_test)
- For monolingual German, the DE–HSB system with 15k vocabulary size and source side BPE-dropout for both the DE–HSB system and its DE–CS parent; 12 times hsb–de data, HSB Sorbian Institute, Witaj, and Web data backtranslated (57.7 BLEU on devel_test).

After the second round of backtranslation, the top configurations were:

- For HSB–DE, the 5k vocabulary size child with source side BPE-dropout for both the HSB–DE system and its CS–DE parent; 20 times hsb–de data, 1.2M lines of (second round) backtranslated DE news (57.15 BLEU on devel_test)
- For monolingual German, the 20k vocabulary size child with source side BPE-dropout for both the DE–HSB system and its DE–CS parent; 12 times hsb–de data, backtranslated (second round) HSB Sorbian Institute, Witaj, and Web data (58.4 BLEU on devel_test).

We note that the second round of backtranslating the German monolingual news data into Upper Sorbian did not improve the BLEU score for the subsequent HSB–DE systems, with the best configuration dropping by 0.1 BLEU points. However, the second round of backtranslation of the Upper Sorbian monolingual data did improve the BLEU score by 0.7 BLEU points for the best configuration, with the vocabulary size of the best configuration increasing to 20k from 15k.

C Pseudo-Sorbian Comparisons and Analysis

Table 7 presents the results of our pseudo-Sorbian comparison discussed in Sections 2.4 and 6.3; as mentioned; we find that both word- and character-level modifications are similar at small vocabulary sizes, but that word-level modification outperforms at a higher vocabulary size. However, at all vocabulary sizes a combination of the two improves over either approach on its own.

It should be noted again that these preliminary results are not directly comparable to other results in this paper (having trained on a smaller corpus, lacking the JW300 documents) and are also not technically constrained (as the word list used to create the character-level replacement was from bilingual dictionaries, not the constrained corpora). In our submitted systems, we created a new character-level system using only the constrained corpora.

As pseudo-Sorbian lexical modification creates a new training corpus, this raises questions of how to appropriately create BPE vocabularies, in particular when the character-level version is used. In word-level pseudo-Sorbian, the resulting corpus still only consists of words found in the original Czech and Upper Sorbian corpora, although the resulting n-gram frequencies will differ somewhat because of some Czech words being replaced by Upper Sorbian ones. Character-level pseudo-Sorbian, however, can create words and character-level n-grams that do not appear in the original corpus at all.[8]

[8] In future work, it would probably be beneficial to guide the output of the modification with a character-level language model trained on target-language data, to better avoid the generation of n-grams that are unlikely or unattested in the target language.

Data	Lines	BPE/Voc.	Parent	Child
train.hsb-de.{de,hsb}	60,000	Y ×25	N	Y
sorbian_institute_monolingual.hsb	339,822	Y ×25	N	Y
web_monolingual_filtered.hsb	131,047	Y ×25	N	Y
witaj_monolingual_filtered.hsb	220,564	Y ×25	N	Y

news-commentary-v15.dedup.de	233,111	N	N	Y

Table 6: Data and how it was used, whether for BPE training and vocabulary extraction, parent model training, or child model training. Note that the monolingual German news.2019 data was subsampled, and the number of lines shown represents the full set from which the subsample was drawn.

Pseudo-Sorbian	BPE 2k	BPE 5k	BPE 10k
Word-level	51.8	52.6	52.6
Character-level	51.9	52.6	52.1
Both	52.4	52.7	**52.8**

Table 7: Comparison of approaches to create Pseudo-Sorbian corpora for pre-training, by word-level or character-level replacement of Czech text, at different vocabulary sizes. All scores represent BLEU scores on dev-test, in the HSB–DE direction.

The systems in Table 7 use system-specific BPE; that is, the BPE operations and vocabulary are constructed for each specific {pseudo-Sorbian, Upper Sorbian} training corpus. However, in the final submitted systems, we used a fixed vocabulary from the original {Czech, Upper Sorbian} corpus, which made it possible to ensemble pseudo-Sorbian systems with our other systems, giving us better results than either type of system alone. We do not know what effect (negative or positive) this may have on the quality of the pseudo-Sorbian-trained systems (since they would be using a BPE vocabulary for a different set of "languages", and thus may be over-segmented).[9] This raises a number of questions about appropriate choices of BPE models, which increases the complexity of ablation studies beyond what we are able to address in the scope of this paper.

Setting aside the complications of various BPE training schemes, we return to the BPE segmentations used in our final systems to analyze whether pseudo-Sorbian and BPE-dropout do indeed achieve their goals of producing more overlap between the pseudo-Sorbian or Czech training data and the Upper Sorbian data. We consider the devel_test portion of the Upper Sorbian data. With a 10k BPE vocabulary, that test set contains 4540 unique subword types. 62.6% of those types (2840) are observed in the baseline Czech parent model training data, and 52.9% of the training tokens are in that set. After applying BPE-dropout to the Czech parent training data, the percentage of observed types increases slightly, to 63.4% (2878), with 58.9% of the training tokens in that set. With the pseudo-Sorbian combined system, however, we see a much bigger increase in type overlap: 89.0% of the Upper Sorbian devel_test types (4041) were observed at least once in the pseudo-Sorbian parent data, making up 70.9% of the training tokens. Increased coverage of Upper Sorbian devel_test subword tokens during parent training means that embeddings for those subword tokens will be updated during parent model training, hopefully in a way that improves their warm start in the Upper Sorbian student training.[10]

[9] Using our final BPE segmentation does result in a slightly higher number of segmentations per token than a BPE model trained directly on the pseudo-Sorbian (combined version) data.

[10] While we could imagine that in some situations, they might end up with inappropriate representations, we expect those to be improved when the tokens are observed in student model training.

CUNI Systems for the Unsupervised and Very Low Resource Translation Task in WMT20

Abstract

This paper presents a description of CUNI systems submitted to the WMT20 task on unsupervised and very low-resource supervised machine translation between German and Upper Sorbian. We experimented with training on synthetic data and pre-training on a related language pair. In the fully unsupervised scenario, we achieved 25.5 and 23.7 BLEU translating from and into Upper Sorbian, respectively. Our low-resource systems relied on transfer learning from German–Czech parallel data and achieved 57.4 BLEU and 56.1 BLEU, which is an improvement of 10 BLEU points over the baseline trained only on the available small German–Upper Sorbian parallel corpus.

1 Introduction

An extensive area of the machine translation (MT) research focuses on training translation systems without large parallel data resources (Artetxe et al., 2018b,a, 2019; Lample et al., 2018a,b). The WMT20 translation competition presents a separate task on unsupervised and very low-resource supervised MT.

The organizers prepared a shared task to explore machine translation on a real-life example of a low-resource language pair of German (de) and Upper Sorbian (hsb). There are around 60k authentic parallel sentences available for this language pair which is not sufficient to train a high-quality MT system in a standard supervised way, and calls for unsupervised pre-training (Conneau and Lample, 2019), data augmentation by synthetically produced sentences (Sennrich et al., 2016a) or transfer learning from different language pairs (Zoph et al., 2016a; Kocmi and Bojar, 2018).

The WMT20 shared task is divided into two tracks. In the unsupervised track, the participants are only allowed to use monolingual German and Upper Sorbian corpora to train their systems; the low-resource track permits the usage of auxiliary parallel corpora in other languages as well as a small parallel corpus in German–Upper Sorbian.

We participate in both tracks in both translation directions. Section 2 describes our participation in the unsupervised track and section 3 describes our systems from the low-resource track. Section 4 introduces transfer learning via Czech (cs) into our low-resource system. We conclude the paper in section 5.

2 Unsupervised MT

Unsupervised machine translation is the task of learning to translate without any parallel data resources at training time. Both neural and phrase-based systems were proposed to solve the task (Lample et al., 2018b). In this work, we train several neural systems and compare the effects of different training approaches.

2.1 Methodology

The key concepts of unsupervised NMT include a shared encoder, shared vocabulary and model initialization (pre-training). The training relies only on monolingual corpora and switches between de-noising, where the model learns to reconstruct corrupted sentences, and online back-translation, where the model first translates a batch of sentences and immediately trains itself on the generated sentence pairs, using the standard cross-entropy MT objective (Artetxe et al., 2018b; Lample et al., 2018a).

We use a 6-layer Transformer architecture for our unsupervised NMT models following the approach by Conneau and Lample (2019). Both the encoder and the decoder are shared across languages.

We first pre-train the encoder and the decoder separately on the task of cross-lingual masked language modelling (XLM) using monolingual

Proceedings of the 5th Conference on Machine Translation (WMT), pages 1123–1128

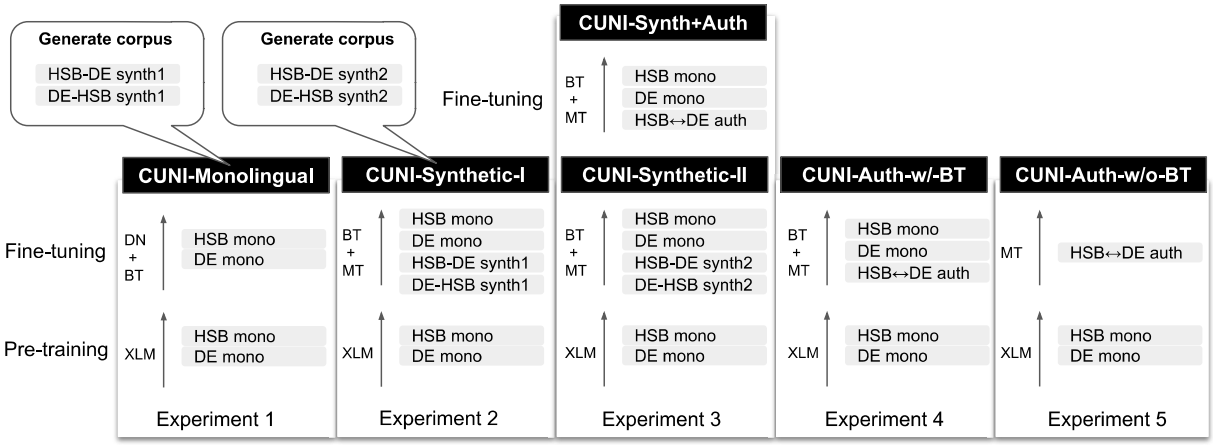

Figure 1: **An overview of selected CUNI systems.** Corpora are illustrated in gray boxes, system names in black boxes. Systems are trained with indicated training objectives: cross-lingual masked language modeling (XLM), denoising (DN), online back-translation (BT), and standard machine translation objective (MT). Monolingual training sets *DE mono* and *HSB mono* were available for both WMT20 task tracks, the parallel training set *HSB↔DE auth* was only allowed in the low-resource supervised track.

data only (Conneau and Lample, 2019). Subsequently, the initialized MT system (*CUNI-Monolingual*) is trained using de-noising and online back-translation. We then use this system to translate our entire monolingual corpus and train a new system (*CUNI-Synthetic-I*) from scratch on the two newly generated synthetic parallel corpora *DE-HSB synth1* and *HSB-DE synth1*. Finally, we use the new system to generate *DE-HSB synth2* and *HSB-DE synth2*, and repeat the training to evaluate the effect of another back-translation round (*CUNI-Synthetic-II*).

All unsupervised systems are trained using the same BPE subword vocabulary (Sennrich et al., 2016b) with 61k items generated using `fastBPE`.[1] An overview of the systems and their training stages is given in fig. 1.

2.2 Data

Our `de` training data comes from News Crawl; the `hsb` data was provided for WMT20 by the Sorbian Institute and the Witaj Sprachzentrum.[2] Most of the `hsb` data was of high quality but we fed the web-scraped corpus (*web_monolingual.hsb*) through a language identification tool `fastText`[3] to identify proper `hsb` sentences. All `de` data was also cleaned using this tool.

The final monolingual training corpora have 22.5M sentences (*DE mono*) and 0.6M sentences (*HSB mono*). Synthetic parallel corpora are generated from the monolingual data sets by coupling the sentences with their translation counterparts as described in section 2.1.

The parallel development (dev) and testing (dev test) data sets of 2k sentence pairs provided by WMT20 organizers are used for parameter tuning and model selection. The final evaluation is run on the blind test set *newstest2020*.

2.3 Results

The resulting scores measured on the blind *newstest2020* are listed in table 1 and table 2. The translation quality metrics BLEU (Papineni et al., 2002), TER (Snover et al., 2006), BEER (Stanojević and Sima'an, 2014) and CharacTER (Wang et al., 2016) provide consistent results. The best quality is reached when using synthetic corpora from the second back-translation iteration, although the second round adds only a slight improvement. A similar observation is made by Hoang et al. (2018) who show that the second round of back-translation does not enhance the system performance as much as the first round. Additionally, the third round does not produce any significant gains.

When training on synthetic parallel corpora, it is still beneficial to perform back-translation on-the-fly (Artetxe et al., 2018b) whereby new training instances of increasing quality are generated in every training step. This method adds 1 - 2 BLEU points to the final score as compared to training

only on sentence pairs from the two synthetic corpora so we use it in all our unsupervised systems.

We used the `XLM`[4] toolkit for running the experiments. Language model pre-training took 4 days on 4 GPUs[5]. The translation models were trained on 1 GPU[6] with 8-step gradient accumulation to reach an effective batch size of 8 × 3400 tokens. We used the Adam (Kingma and Ba, 2015) optimizer with inverse square root decay ($\beta_1 = 0.9$, $\beta_2 = 0.98$, $lr = 0.0001$) and greedy decoding.

3 Very Low-Resource Supervised MT

3.1 Methodology

Our systems introduced in this section have the same model architecture as described in section 2, but now we allow the usage of authentic parallel data. We pre-train a bilingual XLM model and fine-tune with either only authentic parallel data (*CUNI-Auth-w\o-BT*) or both parallel and monolingual data, using a combination of standard MT training and online back-translation (*CUNI-Auth-w\-BT*). Finally, we utilize the trained model *CUNI-Synthetic-II* from section 2 and fine-tune it on the authentic parallel corpus, again using standard supervised training as well as online back-translation (*CUNI-Synth+Authentic)*.

All systems are trained with the same BPE subword vocabulary of 61k items.

3.2 Data

In addition to the data described in section 2.2, we used the authentic parallel corpus of 60k sentence pairs provided by Witaj Sprachzentrum mostly from the legal and general domain.

3.3 Results

The resulting scores are listed in the second part of table 1 and table 2. We compare system performance against a supervised baseline which is a vanilla NMT model trained only on the small parallel train set of 60k sentences, without any pre-training or data augmentation.

Our best system gains 11.5 BLEU over this baseline, utilizing the larger monolingual corpora for XLM pre-training and online back-translation. Fine-tuning one of the trained unsupervised systems on parallel data leads to a lower gain of ∼10 BLEU points over the baseline.

The translation models were trained on 1 GPU[7] with 8-step gradient accumulation to reach an effective batch size of 8 × 1600 tokens. Other training details are equivalent to section 2.1.

4 Very Low-Resource Supervised MT with Transfer Learning

One of the main approaches to improving performance under low-resource conditions is transferring knowledge from different high-resource language pairs (Zoph et al., 2016b; Kocmi and Bojar, 2018). This section describes the unmodified strategy for transfer learning as presented by Kocmi and Bojar (2018), using German–Czech as the parent language pair. Since we do not modify the approach nor tune hyperparameters of the NMT model, we consider our system a transfer learning baseline for low-resource supervised machine translation.

4.1 Methodology

Kocmi and Bojar (2018) proposed an approach to fine-tune a low-resource language pair (called "child") from a pre-trained high-resource language pair (called "parent") model. The method has only one restriction and that is a shared subword vocabulary generated from the corpora of both the child and the parent. The training procedure is as follows: first train an NMT model on the parent parallel corpus until it converges, then replace the training data with the child corpus.

We use the Tensor2Tensor framework (Vaswani et al., 2018) for our transfer learning baseline and model parameters "Transformer-big" as described in (Vaswani et al., 2018). Our shared vocabulary has 32k wordpiece tokens. We use the Adafactor (Shazeer and Stern, 2018) optimizer and a reverse square root decay with 16 000 warm-up steps. For the inference, we use beam search of size 8 and alpha 0.8.

4.2 Data

In addition to the data described in section 3.2, we used the `cs-de` parallel corpora available at the OPUS[8] website: OpenSubtitles, MultiParaCrawl, Europarl, EUBookshop, DGT, EMEA and JRC. The `cs-de` corpus has 21.4M sentence pairs after cleaning with the `fastText` language identification tool.

4.3 Results

We compare the results of our transfer learning baseline called *CUNI-Transfer* with three top performing systems of WMT20. These systems use state-of-the-art techniques such as BPE-dropout, ensembling of models, cross-lingual language modelling, filtering of training data and hyperparameter tuning. Additionally, we also include results for a system we trained without any modifications solely on bilingual parallel data (*Bilingual only*).[9]

The results in table 4 show that training solely on German–Upper Sorbian parallel data leads to a performance of 47.8 BLEU for `de`→`hsb` and 46.7 BLEU for `hsb`→`de`. When using transfer learning with a Czech–German parent, the performance increases by roughly 10 BLEU points to 57.4 and 56.1 BLEU. As demonstrated by the winning system, the performance can be further boosted using additional techniques and approaches to 60.0 and 61.1 BLEU. This shows that transfer learning plays an important role in the low-resource scenario.

[8] `http://opus.nlpl.eu/`

[9] The model *Bilingual only* is trained on the same data as *CUNI-Supervised-Baseline* but uses a different architecture and decoding parameters.

5 Conclusion

We participated in the unsupervised and low-resource supervised translation task of WMT20.

In the fully unsupervised scenario, the best scores of 25.5 (hsb→de) and 23.7 (de→hsb) were achieved using cross-lingual language model pre-training (XLM) and training on synthetic data produced by NMT models from earlier two iterations. We submitted this system under the name *CUNI-Synthetic-II*.

In the low-resource supervised scenario, the best scores of 57.4 (hsb→de) and 56.1 (de→hsb) were achieved by pre-training on a large German–Czech parallel corpus and fine-tuning on the available German–Upper Sorbian parallel corpus. We submitted this system under the name *CUNI-Transfer*.

We showed that transfer learning plays an important role in the low-resource scenario, bringing an improvement of ∼10 BLEU points over a vanilla supervised MT model trained on the small parallel data only. Additional techniques used by other competing teams yield further improvements of up to 4 BLEU over our transfer learning baseline.

Abstract

This paper describes the joint participation of University of Helsinki and Aalto University to two shared tasks of WMT 2020: the news translation between Inuktitut and English and the low-resource translation between German and Upper Sorbian. For both tasks, our efforts concentrate on efficient use of monolingual and related bilingual corpora with scheduled multi-task learning as well as an optimized subword segmentation with sampling.

Our submission obtained the highest score for Upper Sorbian → German and was ranked second for German → Upper Sorbian according to BLEU scores. For English–Inuktitut, we reached ranks 8 and 10 out of 11 according to BLEU scores.

1 Introduction

Our work is motivated by Grönroos et al. (2020), who provide a detailed study of different transfer learning and regularization approaches for low-resource machine translation. They focus on an asymmetric-resource scenario in which the target language is underresourced, but related to a higher-resource language that can be used in a multilingual setting. For example, in the English-to-Estonian task, Estonian is assumed to be a low-resource language (LRL) which is complemented by a second higher-resource target language (HRL), Finnish. Among the WMT 2020 shared tasks, the **German → Upper Sorbian** low-resource translation task exactly corresponds to this setup, with Czech being a high-resource language closely related to Upper Sorbian. We adapt the approach proposed by Grönroos et al. (2020) also to three slightly different scenarios: in the **Upper Sorbian → German** task, the low-resource language is on the source side, but can be complemented with Czech in the same way; for the **English → Inuktitut** task, no related high-resource language is available; and for **Inuktitut → English**, the low-resource language is on the source side and no high-resource language is available.

Grönroos et al. (2020) recommend the combination of the following techniques to reach optimal translation performance in their examined setup:

Scheduled multi-task learning The learning process is split in two phases. The first phase only sees data from the source and the HRL, whereas LRL data is only added in the second phase.

Backtranslation The addition of synthetic data has become a staple of neural machine translation. They recommend marking synthetic data and controlling its weight in the task scheduler.

Subword regularization Following Kudo (2018), each time a word is used during training, a new segmentation into subwords is sampled from the probabilistic segmentation model.

Monolingual tasks In order to benefit from more easily available monolingual data and to make the model more robust to noise, they propose to include denoising sequence autoencoder tasks. A first variant applies small changes to the input side of the corpus (e.g. word deletions, substitutions and reorderings). A second variant, called taboo sampling, relies on the subword regularization idea and generates two maximally different segmentations of the source and target text. For English–Inuktitut,[1] we extend this idea to a transliteration task between romanized and syllabic Inuktitut.

Subword regularization and taboo sampling require the subword segmentation to be based on

[1] We use dashes to refer to language pairs independently of translation direction.

a probabilistic model. While subword regularization has been introduced in conjunction with SentencePiece, Grönroos et al. (2020) show that the EM+Prune variant of Morfessor (Grönroos et al., 2020) outperforms SentencePiece.

The paper is structured as follows. In Section 2, we present the datasets, their sizes and their usage in our submission. Section 3 reports additional experiments with different approaches to word segmentation. Section 4 provides more details about our multi-task approach and the underlying NMT architecture. Section 5 summarizes the results.

2 Data

Both the Inuktitut–English and Upper Sorbian–German tasks can be qualified as low-resource settings, with less than 800K (deduplicated) parallel training instances for the former and 60K for the latter. For both tasks, we follow the constrained setting, which limits the allowed data to those made available on the WMT website. In this section, we present the parallel and monolingual resources that we used for our systems.

2.1 Inuktitut–English

Training data The training resources for the Inuktitut–English tasks are summarized in Table 1. Two allowed parallel resources are provided, the training part of the Nunavut Hansard (NH) corpus (Joanis et al., 2020) and the small WikiTitles corpus. Since the NH training corpus contained a significant proportion of duplicates and preliminary experiments suggested a slight adverse effect of duplicates, we removed them with the OpusFilter tools (Aulamo et al., 2020). We also cleaned the WikiTitles corpus, removing Inuktitut entries not in syllabic script and identical entries. The Inuktitut side of both training corpora was also used to create a parallel corpus for the romanized ↔ syllabic transliteration task. The romanized version was converted from the syllabic one using the *uniconv* + *iconv* pipeline proposed by the corpus providers.

The NH corpus contains a large amount of unaligned data, which we used as additional monolingual corpora. We removed all sentences that were already covered by one of the parallel NH datasets. The English and Inuktitut parts were processed separately. Both parts were backtranslated to the other language using baseline models trained on the parallel corpora, and filters were applied to both sides of the parallel datasets (see below). The Inuktitut unaligned data was used both as a monolingual dataset and as a synthetic parallel dataset for the EN→IU task, whereas the English unaligned data was only used as a synthetic parallel dataset for the IU→EN task (see Table 1).

Among the wealth of monolingual English data provided by WMT, we selected the NewsCommentary corpus and the 2019 sections of NewsCrawl and NewsDiscuss. We produced Inuktitut backtranslations for NewsCommentary and for 2M sentences each (after filtering) of the NewsCrawl and NewsDiscuss corpora. Of the latter two corpora, we held out distinct sets of 1M sentences each for monolingual tasks.

In terms of monolingual Inuktitut data, besides the unaligned NH data, the organizers only provided a CommonCrawl dump. This corpus was again backtranslated to English and filtered. The resulting corpus was used both as a monolingual

Table 2: Training corpora sizes (number of lines) for the German–Sorbian systems. Numbers in italics designate synthetic datasets whose source side is produced by backtranslation.

dataset and as a synthetic parallel dataset for the EN→IU task.

Validation data We used the NH *dev* partition as primary validation set, and the *devtest*, *test* and *NewsDev2020* as secondary validation sets.

Preprocessing All datasets were processed with a translation-direction-specific pipeline. Inuktitut spelling and apostrophe normalization scripts were applied both on source and target sides. The Moses punctuation normalization script was applied only to the English target sides of the parallel corpora. No further preprocessing or tokenization was applied.

Filtering The monolingual and backtranslated parallel corpora were filtered with OpusFilter (Aulamo et al., 2020). The main purpose of this step was to remove too short (i.e., less than 1 word or less than 5 characters on either side) and too long sentences (i.e., more than 300 words or 3000 characters on either side). Furthermore, since crawled input data could be noisy and backtranslation could produce suboptimal results for certain sentences, we applied an additional language model filter based on 5-gram language models trained on the NH training part. Sentences with an average character cross-entropy higher than 30 on either side were removed.

2.2 Upper Sorbian–German

Training data The training data for the Upper Sorbian–German tasks are summarized in Table 2. The organizers provide a parallel German–Sorbian corpus of 60k sentence pairs that we use without further filtering or processing. Moreover, we use four sources of parallel German–Czech data for both directions: the Europarl and JW300 corpora provided on OPUS, as suggested by the organizers, and additionally the Tatoeba and NewsCommentary corpora, which are also available through OPUS (Tiedemann, 2012). The German side of three datasets[2] is backtranslated to Upper Sorbian using a baseline system. The Czech side of the four datasets is backtranslated to Upper Sorbian using an unsupervised character-level translation system (see below). Length filters are applied to all data from external resources (see below).

The organizers provide three monolingual Sorbian corpora: *Sorbian Institute*, a Sorbian *Web Crawl*, and *Witaj*. All corpora are backtranslated to German using a baseline system and filtered.

As monolingual German and Czech resources, we selected the NewsCommentary corpus and the 2018 and 2019 sections of NewsCrawl. These datasets were again filtered. The German datasets were backtranslated to Sorbian.

Validation data We use the *dev* partition as primary validation data and the *devtest* partition as secondary validation data (2000 sentence pairs each).[3]

[2]The full (i.e., unaligned) German version of NewsCommentary is also backtranslated, see below.

[3]The validation and test data for Sorbian consist of fairly short and syntactically simple sentences, which explains why even baseline systems such as those reported in Table 4 obtain BLEU scores around 50.

	Segmentation model and parameters	EN→IU BLEU			IU→EN BLEU		
		Dev	Devtest	Test	Dev	Devtest	Test
0	BPE, raw data, 2k+2k/5k+5k separate, no sampling	24.2	17.9	19.3	41.4	31.4	35.0
1	SentencePiece, raw data, 20k+20k separate, no sampling	23.1	16.9	18.4	36.8	27.2	30.9
2	SentencePiece, raw data, 5k+5k separate, no sampling	24.3	18.0	19.3	40.7	30.9	34.3
3	SentencePiece, raw data, 10k joint, no sampling	24.1	18.0	19.5	40.8	30.8	34.3
4	SentencePiece, dedup data, 10k joint, no sampling	24.2	17.7	19.0	40.7	30.8	34.4
5	SentencePiece, dedup data, 10k joint, with sampling	24.0	17.8	19.2	40.6	30.7	34.4
6	Morfessor, dedup data, 10k joint, no sampling	24.1	17.6	19.0	40.5	30.2	33.9
7	Morfessor, dedup data, 10k joint, with sampling	24.4	18.1	19.3	40.5	30.5	34.2

Table 3: Segmentation model experiments for English–Inuktitut. The baseline model (0) was trained using a Sockeye Transformer with default settings, whereas models 1–7 were trained using OpenNMT-py Transformers with default settings. The segmentation models were trained on the raw or deduplicated versions of the NH training corpus.

For the training phases using exclusively German and Czech data, we use the aligned WMT-News corpus (20 549 sentence pairs), made available on OPUS, as validation set.

Filtering A simple length filter was applied to all corpora sourced from OPUS: sentence pairs where at least one side is empty or longer than 300 words were removed. The same filter was also applied to parallel corpora obtained by backtranslation, which explains the slightly diverging numbers for identical corpora in Table 2.

The Sorbian web crawl was filtered by a 5-gram language model trained on the remaining original Sorbian data. Sentences with a cross-entropy higher than 50 were removed.

All corpus filtering tasks were implemented with OpusFilter (Aulamo et al., 2020). No other preprocessing or tokenization was applied.

Czech–Sorbian backtranslation The task organizers do not provide any Czech–Sorbian parallel corpora that could be used to train a baseline system for producing backtranslations. We therefore resort to unsupervised machine translation. Since Czech and Sorbian are closely related, we extract word n-grams from monolingual corpora and match them using string similarity and frequency criteria.[4] This results in a list of 620k distinct bigram pairs and 230k distinct trigram pairs. They are weighted by frequency to constitute a training corpus for a character-level Czech-to-Sorbian translation system. The translation system is based on bi-directional RNNs with two encoder and two decoder layers. In order to produce backtranslations, the Czech input sentences are chunked into overlapping trigram sequences, translated to Sorbian and merged back again.

[4]We use Europarl, NewsCommentary, Taoeba and WMT-News as Czech monolingual corpora, and Training, Sorbian Institute and Witaj as Sorbian monolingual corpora.

3 Segmentation models

NMT models should ideally be able to represent the entire vocabulary of their source and target languages. The simplest solution however, in which word forms are represented as atomic vocabulary items, leads to sparse statistics, issues with out-of-vocabulary words, and heavy computational costs due to large vocabularies. Moreover, such word-level modeling does not allow the productive recombination of morphemes and is thus unsuitable for morphologically rich languages such as Inuktitut or Sorbian. In recent years, a consensus has emerged that NMT vocabularies should consist of subwords of variable size. Various unsupervised word segmentation algorithms have been proposed, among which byte-pair encoding (BPE) (Sennrich et al., 2016), SentencePiece (Kudo and Richardson, 2018), and several variants of Morfessor (Ataman et al., 2017; Banerjee and Bhattacharyya, 2018; Grönroos et al., 2018, 2020).

Besides the actual word segmentation algorithm, various parameters influence the quality of the resulting translation system:

- Separate word segmentation models for each language or one joint vocabulary for all languages. The joint approach scales better to multilingual models, and enables consistent segmentation of named entities and cognate

		Segmentation model	Translation model	DE→HSB BLEU		HSB→DE BLEU	
	Algorithm	Training data (tokens)	Training data (lines)	Dev	Devtest	Dev	Devtest
1	SentencePiece	0.6M HSB + 0.7M DE	60k	56.93	49.76	57.11	48.74
2	Morfessor	0.6M HSB + 0.7M DE	60k	53.42	46.93	53.93	45.79
3	SentencePiece	8.4M HSB + 8.9M DE	60k	57.39	51.00	57.69	49.91
4	Morfessor	8.4M HSB + 8.9M DE	60k	55.34	48.99	55.51	47.61
5	SentencePiece	8.4M HSB + 8.9M DE + 8.4M CS	60k	57.82	51.30	58.45	49.86
6	Morfessor	8.4M HSB + 8.9M DE + 8.4M CS	60k	56.27	49.76	56.68	48.81
7	SentencePiece	8.4M HSB + 8.9M DE + 8.4M CS	708k / 1931k	61.90	55.06	62.41	53.78
8	Morfessor	8.4M HSB + 8.9M DE + 8.4M CS	708k / 1931k	61.56	55.04	62.16	53.83

Table 4: Segmentation model experiments for German–Upper Sorbian. All segmentation models are joint models with 20 000 units, but trained on variable amounts of data. All translation models are OpenNMT-py Transformers with default settings with active subword sampling, trained either without (1–6) or with (7–8) additional backtranslations.

words across languages, assuming they are written in the same script.

- The chosen vocabulary size and the amount of training data from which the segmentation model is learned. Denkowski and Neubig (2017) recommend a vocabulary size of 32k units, trained jointly on all languages, for normal-sized datasets. In contrast, Ding et al. (2019) obtain the best results with small vocabularies of only 500 units in low-resource scenarios. Optimal vocabulary size varies thus depending on the size of the parallel and monolingual data.

- If the segmentation algorithm is based on a probabilistic model (such as SentencePiece or Morfessor), it can be used to sample different segmentations for any given word. This technique is known as subword regularization (Kudo, 2018) and has been shown to improve the robustness of translation models.

Grönroos et al. (2020) tested various segmentation model configurations on a multilingual translation task and obtained best results with Morfessor EM+Prune, followed by SentencePiece and BPE. Furthermore, when trained on the same amount of data and using subword regularization, the vocabulary size (tested between 5K and 20K entries) turned out to be irrelevant for both SentencePiece and Morfessor EM+Prune.

We carried out some additional experiments with the English–Inuktitut task, which differs from their setup in the sense that the languages use different scripts and there is no third language involved. Table 3 compares different parameter settings with the baseline results provided by the organizers (Joanis et al., 2020). A first set of experiments shows that the vocabulary size does matter when not using subword sampling (1 vs 2), but that separate and joint segmentation models perform equivalently (2 vs 3). SentencePiece does not perform better than BPE (2 vs 0), although different preprocessing choices may be responsible for the generally lower results obtained in the IU→EN direction. The second set of experiments shows that Morfessor EM+Prune lags slightly behind SentencePiece when not using sampling (6 vs 4), but that sampling has a more beneficial effect to Morfessor EM+Prune than to SentencePiece (7 vs 6, 5 vs 4).

For German–Upper Sorbian, the setup differs from Grönroos et al. (2020) with respect to the amount of available training data. We therefore ran additional experiments to measure the impact of both the training data used for the segmentation model and the training data used for the translation model. Table 4 summarizes our findings. All experiments are based on joint word segmentation models with a total of 20K vocabulary items.

When training both the segmentation model and the translation model on the provided parallel data (experiments 1 and 2), SentencePiece performs much better than Morfessor EM+Prune. The addition of monolingual training data for the segmentation model (experiments 3 and 4) helps both segmentation algorithms about equally well (+ 1–2 BLEU). In contrast, the further addition of Czech data for the segmentation model (experiments 5 and 6) benefits Morfessor more than SentencePiece on average.[5] Finally, augmenting the trans-

[5]The additional monolingual Sorbian data comes from the

	Training data	Weighting	Monoling. tasks	EN→IU BLEU NH Dev	EN→IU BLEU Newsdev	IU→EN BLEU NH Dev	IU→EN BLEU Newsdev

2	EN↔IU + BT	✓	Noise + Translit.	*25.15	*15.95	**41.89**	33.47
3	EN↔IU + BT	✓	Noise + Taboo	**25.28**	**16.15**	*41.67	***33.49**

Table 5: Inuktitut translation experiments. Systems marked with * were used for the final primary submissions.

lation model training data with backtranslations obviously increases the overall translation scores, but also brings Morfessor EM+Prune on par with SentencePiece.

We were thus not able to reproduce the substantial gains in translation quality with Morfessor EM+Prune observed by Grönroos et al. (2020). Rather, we found that SentencePiece was generally more robust to different data conditions and setups. Nevertheless, Morfessor EM+Prune remains competitive with its default parameters if subword sampling is enabled and the training data are carefully chosen. For the final Inuktitut models, we decided to used configuration 7 from Table 3, since it allowed us to use monolingual tasks relying on subword sampling. For the final Sorbian models, we used configuration 8 from Table 4.

4 Translation models

All our models are based on the Transformer architecture and use, by and large, the same hyperparameters as Grönroos et al. (2020). The Transformer contains 8 encoder and 8 decoder layers with 16 attention heads each. The hidden layer size is 1024, the filter size 4096. The minibatch varies between 7200 and 9200 tokens, depending on the task, and gradients are accumulated over 4 minibatches. All models were trained for 200 000 steps, which corresponded to 5–7 days training time on a single V100 GPU. The best savepoint was selected on the basis of development set accuracy; this measure turned out to be more stable than development set BLEU score.

We use the *dynamicdata* branch of the OpenNMT-py toolkit (Klein et al., 2017) for our experiments.[6] This branch provides the necessary adaptations for the techniques introduced by Grönroos et al. (2020): scheduled multi-task learning requires the ability to adjust the task mix during training, whereas subword regularization and the denoising sentence autoencoder task require sampling fresh noise for each minibatch.

The experiments presented in Tables 3 and 4 already confirmed the positive impact of subword regularization and backtranslation. Row 1 of Tables 5 and 6 provide baseline results with these two techniques. Backtranslated training instances are marked with a special token.

Scheduled multi-task learning As row 2 in Table 6 shows, the mere inclusion of a German↔Czech task with language labels but without any task scheduling already increases BLEU scores by 1.5 points. However, simple transfer learning setups such as this are prone to catastrophic forgetting, especially in low-resource settings such as ours.

Kiperwasser and Ballesteros (2018) propose a general strategy called scheduled multi-task learning, in which different tasks are mixed according to a task-mix schedule. Grönroos et al. (2020) propose a partwise constant task-mix schedule with an arbitrary number of steps, any of which can be mixing multiple tasks. This flexibility is useful when training with a large number of heterogeneous tasks: multiple language pairs with different amounts of data, data from different domains (oversampling the in-domain data), natural vs synthetic (e.g. back-translated) data, and auxiliary tasks (e.g. autoencoder).

A training schedule with two phases (row 3 in Table 6) further increases scores slightly. Details of the schedule and the task weights are given in Table 7.

Witaj and Sorbian Institute corpora. We added an equivalent amount of German data from NewsCommentary and WMT-News. The Czech data also stems from NewsCommentary and WMT-News and is complemented by a subset of Czech Europarl.

[6] https://github.com/Waino/OpenNMT-py
The functionality of the *dynamicdata* branch is included by default in the upcoming release v2.0 of OpenNMT-py, albeit in a different implementation.

4.1 Monolingual tasks

Denoising sequence autoencoder task. In the denoising autoencoder (Vincent et al., 2008; Hill et al., 2016) clean text is corrupted by sampling from a noise model, and fed in as a pseudo-source. The target is a reconstruction of the clean input. The goal of the autoencoder tasks is to use monolingual data to strengthen target language modeling in the decoder and source language understanding in the encoder. In addition, the autoencoder task acts as regularization. Noise has been used as a regularizer in many NLP techniques, including dropout (Srivastava et al., 2014), label smoothing (Szegedy et al., 2016), SwitchOut (Wang et al., 2018), and subword regularization (Kudo, 2018). Sampling fresh noise for each minibatch is important, especially in low-resource conditions where the small data set is reused for many epochs. The denoising sequence autoencoder has previously been applied to language model pretraining in BART (Lewis et al., 2019).

Typical noise models for denoising sequence autoencoder apply small changes to the input side of the corpus: local reordering (Lample et al., 2018), deletions (Iyyer et al., 2015), insertions (Vaibhav et al., 2019), substitutions (Wang et al., 2018), and masking (Devlin et al., 2019). Of these, our method applies local reordering and token deletion.

Taboo sampling segmentation task. Grönroos et al. (2020) propose taboo sampling, a noise model extending the subword regularization idea specifically for monolingual data. It takes in monolingual text and generates two maximally different segmentations, e.g. *dys* + *functional* on the source side and *dysfunction* + *al* on the target side. During taboo sampling, all multi-character subwords used in the first segmentation have their probability temporarily set to zero, to ensure that they are not used in the second segmentation.

Transliteration task. As an alternative to taboo sampling, we take advantage of the fact that Inuktitut can be written in two different scripts, romanized and syllabic. Since the segmentation model is trained only on syllabic Inuktitut (and the occasional romanized proper name occurring on the English side of the NH corpus), we assume that the same word will be segmented very differently in the two scripts, leading to a similar effect as taboo sampling. We include a romanized→syllabic transliteration task in the EN→IU model, and a syllabic→romanized task in the IU→EN model.

Experiments 2–3 in Table 5 as well as experiments 4–5 in Table 6 explore different combinations of monolingual tasks. For Inuktitut, the addition of monolingual tasks increases BLEU scores markedly, but there is no clear winner between the transliteration and taboo tasks. For Sorbian, the monolingual tasks only help when translating towards German, but not when translating towards Sorbian. One reason for this somewhat surprising finding could be that the Sorbian monolingual data is identical with the Sorbian target of the backtranslations, so that no additional data is added with the monolingual tasks.

5 Submissions and results

For the best-performing configurations, we trained two models each, one ("basic") with the hyperparameters listed above, and an alternative one with relative position distance clipping at 4 (see Shaw et al., 2018). However, this setting did not yield any consistent accuracy gains or losses.

For the **Inuktitut** task, we submitted single systems of settings 2 and 3 for both directions. For EN→IU, the alternative model of setting 2 obtained the best scores on the test set (10.1 BLEU / 0.301 chrF), whereas for IU→EN, the basic model of setting 3 obtained the best scores on the test set (23.0 BLEU / 0.455 chrF). Among the 11 primary submissions in both translation directions, our sub-

	EN→IU	IU→EN		DE→HSB		HSB→DE	
Training steps	0–200k	0–200k	Training steps	0–60k	60–200k	0–60k	60–200k
Bilingual	45%	45%	Bilingual DE↔CS	90%	50%	85%	25%
Backtranslation	40%	40%	Bilingual DE↔HSB		20%		30%
Noise EN	5%	5%	Backtr. DE↔HSB		20%		30%
Noise IU	5%	5%	Backtr. HSB→CS			5%	5%
Taboo IU / Translit. rom.→syll.	5%		Noise / Taboo DE	5%		5%	5%
Taboo EN / Translit. syll.→rom.		5%	Noise / Taboo CS	5%		5%	
			Noise / Taboo HSB		10%		5%

Table 7: Task schedules for the Inuktitut (left) and Sorbian (right) experiments.

mission obtained rank 8 for EN→IU and rank 10 for IU→EN in terms of (inofficial) BLEU scores. It will be instructive to examine the manual evaluation results and the other system descriptions to identify the reasons behind these rather disappointing results.

For the **Sorbian** task, we submitted ensembles of the basic and alternative models. Setting 3 turned out to be the best choice for DE→HSB (57.9 BLEU / second rank), and setting 4 for HSB→DE (59.6 BLEU / first rank). For both directions, ensembling has raised the BLEU scores by 0.6. Our submissions would obtain first rank in both directions if only single systems were considered.

6 Conclusion

In this work, we tested various methods for low-resource machine translation proposed by Grönroos et al. (2020) on the English–Inuktitut and German–Upper Sorbian tasks in WMT 2020. In particular, we investigated several subword segmentation approaches and the inclusion of monolingual tasks.

In terms of **subword segmentation**, we were not able to reproduce the reported gains for the Morfessor EM+Prune method over SentencePiece. We obtained comparable results with both methods though. We also found that increasing the size of segmentation model training data was useful, and that Morfessor EM+Prune was more sensitive to training data size than SentencePiece. Furthermore, we obtained slight improvements from subword sampling, confirming earlier results.

During the development phase, we also found curious interactions between the subword vocabulary size and different NMT toolkits. We were able to reproduce the organizer-provided Inuktitut baselines with both small and large vocabularies using the Sockeye toolkit, but obtained significantly lower scores with OpenNMT-py and large vocabularies, even after harmonizing the training hyper-parameters between toolkits. With small subword vocabularies, OpenNMT-py became competitive again.

The inclusion of **monolingual tasks** yielded clear improvements for the Inuktitut experiments. The noise model had the most positive effect, whereas the transliteration and taboo sampling tasks showed minor effects. In contrast, the effect of the monolingual tasks on the Sorbian experiments was more subtle. The **two-phase training schedule** introduced by Grönroos et al. (2020) proved useful in the Sorbian experiments.

Abstract

We describe NITS-CNLP's submission to WMT 2020 unsupervised machine translation shared task for German language (de) to Upper Sorbian (hsb) in a constrained setting i.e, using only the data provided by the organizers. We train our unsupervised model using monolingual data from both the languages by jointly pre-training the encoder and decoder and fine-tune using backtranslation loss. The final model uses the source side (de) monolingual data and the target side (hsb) synthetic data as a pseudo-parallel data to train a pseudo-supervised system which is tuned using the provided development set(dev set).

1 Introduction

This paper provides the system description of the unsupervised neural machine translation system for German to Upper Sorbian submitted by the Center for Natural Language Processing of National Institute of Technology, Silchar, India (NITS-CNLP) in the WMT 2020 shared task for Unsupervised and Very Low Resource machine translation for German and Upper-Sorbian language pair. Specifically, we made our primary submission for the unsupervised task in $de \rightarrow hsb$ direction. We use the data provided by the organisers only i.e, in a constrained manner. Our unsupervised neural machine translation (UNMT) system first pre-trains a transformer (Vaswani et al., 2017) based encoder and decoder model using masked sequence to sequence (MASS) pre-training (Song et al., 2019) and fine-tune using the back-translation (Sennrich et al., 2016a) loss. The final model trained using MASS objective is then used to translate the source side (M_{de}) monolingual data into a synthetic target side data ($M^{'}_{hsb}$)and then train a pseudo-supervised model using $\{M_{de}$,$M^{'}_{hsb}\}$ from scratch.

The remaining of the paper is arranged in following manner: Section 2 gives a brief background of an unsupervised MT. Section 3 describes the data preprocessing. In Section 4, we describe our UNMT system. The results and analysis are shown in Section 5. Finally, Section 6 concludes the paper.

2 Background

NMT (Kalchbrenner and Blunsom, 2013; Cho et al., 2014; Bahdanau et al., 2014) has become the de-facto MT system in recent times achieving near human level translation quality for many language pair however at the cost of millions of bi-text data. Unfortunately, bi-text data for many languages is scarce or non-existent. Unsupervised MT (Lample et al., 2018a; Artetxe et al., 2018b) is one of the techniques to handle the bi-text unavailability by exploiting monolingual data (Sennrich et al., 2016a). Primitive unsupervised MT first maps the monolingual data into a common cross-lingual shared vector embedding space (Conneau et al., 2017; Artetxe et al., 2017) and infer a bilingual dictionary from this shared space using adversarial training (Lample et al., 2018a) or through self learning (Artetxe et al., 2018b) and further improve the model through a combination of de-noising auto-encoder and iterative or on-the-fly back-translation. Subsequently, this principle has been applied in SMT (Lample et al., 2018b; Artetxe et al., 2018a) or a combination of NMT and SMT (Marie and Fujita, 2018; Ren et al., 2019) to further improve the unsupervised MT. However, in this work, we follow a newer approach of cross-lingual language model pretraining (Lample and Conneau, 2019; Song et al., 2019) which has shown to be a stronger initialization for unsupervised MT than the cross-lingual shared vector embedding space.

3 Data and Preprocessing

This section is further divided into two subsections briefing the data description and the preprocessing steps used.

Proceedings of the 5th Conference on Machine Translation (WMT), pages 1139–1143

Corpus		Sentences
mono	de (News Crawl)	5 **M**
	hsb	756.3 **K**
dev/test	de	2 **K**
	hsb	2 **K**

Table 1: Statistics of the monolingual and the dev/test set.

3.1 Data Description

We use a randomly sampled 5**M** monolingual corpus for German side from News Crawl[1] dataset, while we use all the available monolingual data[2] and the parallel side[3] of Upper Sorbian[4] as the combined monolingual data for the same and summing up 756,271 number of sentences. For tuning and evaluation[5], we use the provided devtest[6] data with 2000 sentences for both the dev and test files as shown in Table 1.

3.2 Preprocessing

We use `Moses`(Koehn et al., 2007) toolkit for preprocessing the data. The corpus underwent removal of non-printing characters and tokenization. For the Upper Sorbian, we used Czech `(cs)` language code for tokenization as Upper Sorbian `(hsb)` language code is unavailable in `Moses` toolkit[7] and considering the relatedness of these languages[8].

The above preprocessing is used by MASS pretrain and MASS finetune models while the pseudo-supervised model uses the raw data and learns a Sentencepiece BPE. The details are described in Section 4.2.

4 UNMT System

Our UNMT system is a pipeline of encoder-decoder pretraining and fine-tuning using MASS (Song et al., 2019) and using the synthetic data generated (M'_{hsb}) from the source monolingual data (M_{de}) to train a forward model from scratch. This section is further divided into two subsections, first describing the MASS pretraining and fine-tuning and second, the transformer based forward ($\overrightarrow{f}$) pseudo-supervised model using the pseudo-parallel ($\{M_{de}, M'_{hsb}\}$) data by inducing Lample et al. (2018a) style noise (word drop, word shuffle and word blank) upon the input data.

```
--mass_steps 'de,hsb'
--encoder_only false
--emb_dim 1024 --n_layers 6
--n_heads 8 --dropout 0.1
--attention_dropout 0.1

--tokens_per_batch 3000
--optimizer adam_inverse_sqrt,
  beta1=0.9,beta2=0.98,lr=0.0001
--word_mass 0.5 --min_len 5
```

Table 2: `MASS` pretraining parameters

4.1 MASS Pretrain and Finetune

We use the `MASS` toolkit[9] to pretrain a cross-lingual language model using the masked sequence to sequence objective. Initially, the corpus are segmented into subword units using BPE(Sennrich et al., 2016b). A joint BPE is learnt over the monolingual data of both the languages (German and Upper Sorbian) and the vocabulary is limited to 60,000 shared vocabulary tokens.

MASS Pretraining: The BPE tokenized monolingual data is used to pretrain the encoder and decoder jointly by the cross lingual MASS objective and the training is done for 100 epochs. The parameters for the `MASS` pretraining is shown in Table 2.

MASS Fine-tuning: The pretrained model is capable to generate translations but it is merely a copy task. So, in order to make the model more robust, it is further fine-tuned using the loss objective of back-translation. The fine-tuning is halted after the 10th epoch before being converged due to resource limitation. The parameters for fine-tuning is listed in Table 3.

4.2 Pseudo-Supervised NMT

We follow Marie et al. (2019) style of using the pseudo-parallel data generated from a previous

--eval_bleu true
```

Table 3: MASS finetuning parameters

model to train a forward pseudo-supervised model. In our case, we first generate a synthetic data (M'_{hsb}) from the source monolingual data (M_{de}) using beam search decoding with a beam size of 10 from the MASS fine tuned model. Unlike Marie et al. (2019) where back translation was applied, we use forward translation from the source side monolingual (He et al., 2020) data to generate synthetic data. The synthetic data is detokenized, and we learn a joint subword BPE from the raw M_{de} and M'_{hsb} using Sentencepiece (Kudo and Richardson, 2018) and limit the shared vocabulary to 10 **K** units.

Noisy Pseudo-Supervised NMT: We add perturbations or noise, specifically we apply word dropout, word shuffle and word blank to our synthetic data. This kind of perturbation is found to be effective for overcoming the local minima by enforcing local smoothness (He et al., 2020; Shen et al., 2019). We train our pseudo-supervised NMT in a pseudo self-training approach by leveraging the source side monolingual data. This self-training is partial in the sense that we only use the pseudo-parallel data which lacks any sort of real labelled data for a single iteration.

The pseudo-supervised NMT is trained from scratch using Fairseq (Ott et al., 2019) toolkit[10] i.e, we do not use the previous models weights rather we apply random weight initialization for our new model. The model is trained for 300 **K** update steps. We follow Guzmán et al. (2019) style transformer architecture of 5 encoder and decoder layers, 512 embedding dimension, the feed-forward hidden dimension is 2048 with 4 multi-head attentions[11]. The rest of the parameters are listed in Table 4. We

Table 4: Pseudo-supervised NMT training parameters

make our primary submission of the test source generated using a beam search decoding with beam size of 5 and a length penalty of 1.2.

5 Result

The official automatic evaluation uses the the following metrics: BLEU (Papineni et al., 2002), TER (Snover et al., 2006), BEER (Stanojević and Sima'an, 2014), and CharactTER (Wang et al., 2016). Our primary submission (NITS-CNLP), the pseudo-supervised NMT achieves a cased BLEU of 15.4 and 15.8 as the uncased BLEU score on the *newstest2020* blind-test data. The scores are reported in Table 5. We also present the sample input-output of our primary system (NITS-CNLP) from two randomly selected test sentences from the matrix[12] in Table 6. We also report the Sacrebleu score of our various settings with the released test set (non blind test) in Table 7.

6 Conclusion

We report here the system description for our submission to the WMT 2020 shared task of Unsupervised MT for German-Upper Sorbian language pair. We submit our pipelined architecture of masked sequence to sequence pretraining along with finetuning and a pseudo-supervised model in German to Upper Sorbian direction. We observe that the performance of an unsupervised model improves significantly over the base MASS pretraining and

finetuning after using the synthetic data to train a pseudo-supervised model using a very naive way of self-training i.e, we have just used a single iteration of our forward training. Synthetic data is the *de-facto* for any modern semi-supervised MT system and in this experiment we show that synthetic data in an unsupervised MT is effective and also emphasised the importance of a pseudo-supervised MT model as a refinement step to an unsupervised MT.

Adobe AMPS's Submission for Very Low Resource Supervised Translation Task at WMT20

Keshaw Singh
AI/ML Platform & Solutions, Adobe Inc.
Bengaluru, India
kessingh@adobe.com

Abstract

In this paper, we describe our systems submitted to the very low resource supervised translation task at WMT20. We participate in both translation directions for Upper Sorbian-German language pair. Our primary submission is a subword-level Transformer-based neural machine translation model trained on original training bitext. We also conduct several experiments with backtranslation using limited monolingual data in our post-submission work and include our results for the same. In one such experiment, we observe jumps of up to 2.6 BLEU points over the primary system by pretraining on a synthetic, backtranslated corpus followed by fine-tuning on the original parallel training data.

1 Introduction

This paper describes our submissions to the shared task on Very Low Resource Supervised Machine Translation at WMT 2020. The task involved a single language pair: Upper Sorbian-German. We submit supervised neural machine translation (NMT) systems for both translation directions, Upper Sorbian→German and German→Upper Sorbian.

NMT models (Sutskever et al., 2014; Bahdanau et al., 2015; Cho et al., 2014a) have achieved state-of-the-art performance on benchmark datasets for multiple language pairs. A big advantage of such systems over phrase-based statistical machine translation (PBSMT) (Koehn et al., 2003) models is that they can be trained end-to-end. The bulk of the development, however, has been limited to a handful of high-resource language pairs. The primary reason is that training a well-performing NMT system requires a large amount of parallel training data, which means a lot of equivalent investment in terms of resources. Koehn and Knowles (2017) show that when compared to PBSMT approaches, NMT models need more training data to achieve the same level of performance.[1] One of the most popular ways to increase the amount of parallel training data for supervised training is backtranslation (Sennrich et al., 2016a). We utilize this approach to improve upon the performance of our baseline models.

All of our systems follow the Transformer architecture (Vaswani et al., 2017). Our primary system is a supervised NMT model trained on the original training bitext. We also report our results on experiments with backtranslation, which were completed post the shared task and hence not a part of our primary submissions. We use the backtranslated data in two distinct ways - as a standalone parallel corpus, and to create a combined parallel corpus by mixing in a 1:1 ratio with the provided training data. We also report the performance of fine-tuned models originally trained only on the backtranslated data. In the following sections, we begin by briefly describing the Transformer architecture and backtranslation. We then discuss our experimental setup as well as our experiments with backtranslation. We conclude with a discussion of our results and possible future work.

2 Related Work

The Transformer model is the dominant architecture within current NMT models due to its superior performance on several language pairs. While still a sequence-to-sequence (Sutskever et al., 2014) model composed of an encoder and a decoder, Transformer models are highly parallelizable thanks to being composed purely of feed-forward and self-attention layers rather than recurrent layers (Hochreiter and Schmidhuber, 1997; Cho et al., 2014b). The reader is encouraged to read the original paper (Vaswani et al., 2017) to gain a deeper understanding of the model. We adopt the Transformer base architecture available under the

[1] As measured by BLEU score (Papineni et al., 2002).

Proceedings of the 5th Conference on Machine Translation (WMT), pages 1144–1149

fairseq[2] (Ott et al., 2019) library for all our models.

However, NMT models are known to be data-hungry (Koehn and Knowles, 2017); their performance improves sharply with the availability of more parallel training data. Except for a few language pairs (e.g. English-German), most have little to no such data available. On the other hand, a far greater number of languages have a decent amount of monolingual data available online (e.g. Wikipedia).

To address this issue of lack of parallel data, Sennrich et al. (2016a) introduced the concept of back-translation. It involves creating a synthetic parallel corpus by translating sentences from the target-side monolingual data to the source language and making corresponding pairs. A baseline target→source model (PBSMT or NMT), trained with limited data, is generally used for this purpose. It enables the use of large corpora of monolingual data for several languages, the size of which is typically orders of magnitude larger than any corresponding bitext available. What is notable is that only the source-side data is synthetic in such a scenario and the target-side still corresponds to original monolingual data.

Some studies (Poncelas et al., 2018; Popel, 2018) have investigated the effects of varying the amount of backtranslated data as a proportion of the total training corpus, including training only on the synthetic dataset as a standalone corpus. We follow some of the related experiments conducted by Kocmi and Bojar (2019) on Gujarati-English (another low-resource pair) with a few exceptions. Besides, we also report performance when pretraining solely on the synthetic corpus following by fine-tuning on either original or mixed data. While not quite the same, one could think of this approach as having some similarities with transfer learning (Zoph et al., 2016) as well as domain adaptation (Luong and Manning, 2015; Freitag and Al-Onaizan, 2016) for machine translation. There has also been work on using sampling (Edunov et al., 2018) for generating backtranslations, but we stick to using beam search in this work.

3 Experimental Setup

3.1 Dataset

We used the complete parallel training corpus for our primary systems. In addition, we also made use of monolingual data from each language for two purposes - learning Byte Pair Encodings (BPE) (Sennrich et al., 2016b) and backtranslation. For Upper Sorbian (hsb), we used the monolingual corpora provided by the Sorbian Institute and by the Witaj Sprachzentrum. To control the quality of the backtranslated data, we chose not to use the data scraped from the web. For the German (de) side, we made use of the News Crawl[3] 2009 dataset, as it is large enough to satisfy the requirements for our experiments.

3.2 Data Preprocessing

Source	No. of sentences
hsb-de, bitext	58,389
hsb, monolingual	540,994
de, monolingual	2,000,000

Table 1: Processed training data.

Moses toolkit (Koehn et al., 2007) was used for tokenization and punctuation normalization for all data. Before doing any additional preprocessing, we learned separate truecaser models using the toolkit. For this purpose, we took first 500K sentences from each of the monolingual corpora and aggregated them with the corresponding portion from the training bitext. After tokenizing and truecasing, we joined the parallel training corpus with the same monolingual data. We learned joint BPE[4] with 32K merge operations over this corpus and applied them to the parallel training data to get vocabularies for each language. Additionally, we used the `clean-corpus-n.perl` script within Moses to filter out sentences from the parallel corpus with more than 250 subwords as well as sentence length ratio over 1.5 in either direction. Final corpus statistics are presented in Table 1.

3.3 Training

Our primary system is a Transformer base model, trained on the parallel training corpus for both translation directions till 60 epochs. We keep most of the hyperparameters to their default values in fairseq. More precisely, we chose Adam (Kingma and Ba, 2015) as the optimizer and Adam betas were set to 0.9 and 0.98, respectively. The maximum number of tokens in each batch was set to 4096. Learning rate was set to 0.0005, with an inverse squared

[2] https://github.com/pytorch/fairseq

[3] http://data.statmt.org/news-crawl/de/

[4] https://github.com/glample/fastBPE

root decay schedule and 4000 steps of warmup updates. Label smoothing was set to 0.1 and dropout to 0.3. Label-smoothed cross-entropy was used as the training criterion.

We trained all our models for a fixed number of epochs, determined separately for each system, and chose the last checkpoint for reporting BLEU (Papineni et al., 2002) scores on the test sets.

All training was done using a single NVIDIA P100 GPU. Due to the small amount of parallel training data, each epoch of training took about 90 seconds on average for the primary system.

4 Additional Backtranslation Experiments

In this section, we report our post-submission work on using monolingual data for backtranslation. We took the raw monolingual data that we describe in Section 3.1 and backtranslated with our primary submission models for the respective translation directions, i.e., hsb→de for Upper Sorbian data and de→hsb for German data. We used `fairseq-generate` function with a beam size of 5 for this purpose. Once again, we limited the number of subwords in each sentence to 250. Finally, we took all sentence pairs for backtranslated Upper Sorbian corpus and the first two million sentence pairs for the German corpus. Table 1 indicates the size of the backtranslated corpora by original language. For further experiments, we name the datasets as follows:

- *auth*: Processed original training data.
- *synth*: Backtranslated de→hsb and hsb→de corpora.
- *mixed*: Augmented training data obtained by mixing *auth* with a portion of *synth* in 1:1 ratio, providing a total of 116,778 sentence pairs.

We define the following systems for making use of the backtranslated data. Note that the first system only differs from the primary system in the number of training epochs completed.

- *auth-from-scratch*: This system has the same settings as the primary system. It was trained on the *auth* corpus till 80 epochs (as opposed to 60 for primary).
- *mixed-from-scratch*: We trained models on *mixed* data from scratch for 40 epochs.[5]
- *synth-from-scratch*: Models were trained only on the *synth* datasets. To adjust for the difference in the size of the respective backtranslated corpora, we trained hsb→de system for 10 epochs and de→hsb system for 30 epochs.
- *synth-auth-finetune*: We took the models trained via the previous system and fine-tuned them on *auth* data for 20 epochs in each translation direction.
- *synth-mixed-finetune*: Same as the last model, except that fine-tuning was done on *mixed* data.

Fine-tuning was carried out by loading pretrained checkpoints and adding extra training flags in `reset-optimizer` and `reset-lr-scheduler`.

5 Results

The systems were evaluated on the blind test set (newstest2020) using automated metrics; no human evaluation was done. Table 2 shows cased BLEU scores for various systems. Our primary systems achieved a BLEU score of 47.6 for Upper Sorbian→German and 45.2 for German→Upper Sorbian translation. We achieved an improvement of 0.3 and 0.4 BLEU points, respectively, by training further till 80 epochs in each direction. We also evaluated a third system, *synth-auth-finetune*, as described in Section 4, which provided a jump of 2.6 points in BLEU score over the primary system for Upper Sorbian→German and 2.5 for German→Upper Sorbian.

In addition to evaluating on blind test sets, we also report BLEU scores on the development test set in the same table. Two outcomes are worth highlighting:

- Model trained only on *synth* data for German→Upper Sorbian translation matched the performance of a similar model trained on the authentic bitext.
- Best results were obtained by fine-tuning a model trained on *synth* data with either *auth* or *mixed*.

[5]We trained further till 60 epochs, but observed no improvement in BLEU scores.

System	Dataset	Epochs	newstest2020	devtest
			hsb→de	
Primary*	*auth*	60	47.6	-
auth-from-scratch	*auth*	80	47.9	45.6
mixed-from-scratch	*mixed*	40	-	45.7
synth-from-scratch	*synth*	10	-	38.0
synth-auth-finetune	*+auth*	20	**50.2**	**49.6**
synth-mixed-finetune	*+mixed*	20	-	48.3
			de→hsb	
Primary	*auth*	60	45.2	-
auth-from-scratch	*auth*	80	45.6	46.4
mixed-from-scratch	*mixed*	40	-	47.4
synth-from-scratch	*synth*	30	-	46.5
synth-auth-finetune	*+auth*	20	**47.7**	49.0
synth-mixed-finetune	*+mixed*	20	-	**49.6**

Table 2: BLEU scores for the blind test set (newstest2020) and the development test set. Bold values in a column indicate the best scores among the evaluated systems. + Additional fine-tuning for models trained with backtranslated corpora. * Only the primary systems were evaluated before deadline.

The second result is notable since the regime of pretraining followed by fine-tuning improves the BLEU scores by up to 4 points on this test set when compared to training only on the original bitext. Moreover, while the model trained on *synth* was not able to match the performance of that trained on *auth* for Upper Sorbian→German, it still provides the same benefits as German→Upper Sorbian model when fine-tuned further. Looking at the small improvements achieved by using only the *mixed* corpus for training, increasing its size by combining upsampled *auth* data with more *synth* data might lead to even further jumps in the BLEU scores.

6 Conclusion

In this paper, we described our Transformer model for supervised machine translation for Upper Sorbian-German language pair. We take note of relatively high BLEU scores achieved by our primary systems (and those of other participants) on this low-resource language pair, which could relate to the high quality of the training corpus. We also report results and takeaways from several experiments with backtranslated data completed post the shared task. A key result is matching the performance of a system trained on the original bitext with one trained on a limited amount of synthetic, backtranslated data. Domain mismatch and a difference in the quality of monolingual corpus might have prevented the system from achieving a similar result in the other direction. We notice big improvements in performance over the primary systems by following a "pretraining then fine-tuning" regime.

An interesting future work would be to measure the applicability of this approach to other low-resource language pairs. Additional systems could be added as well. For instance, models trained on *mixed* data and fine-tuned on *auth* data might provide a meaningful comparison. Prior work (Ding et al., 2019) has shown that the number of BPE merge operations has a significant effect on the performance of NMT systems. This work was pointed out during the review process and should be an avenue for further improvement of the model performance.

Acknowledgments

The author would like to thank his manager for supporting this project, and the anonymous reviewers for their thoughtful comments which helped improve the presentation of this work.

On the Same Page? Comparing Inter-Annotator Agreement in Sentence and Document Level Human Machine Translation Evaluation

Sheila Castilho

sheila.castilho@adaptcentre.ie

Abstract

Document-level evaluation of machine translation has raised interest in the community especially since responses to the claims of "human parity" (Toral et al., 2018; Läubli et al., 2018) with document-level human evaluations have been published. Yet, little is known about best practices regarding human evaluation of machine translation at the document-level. This paper presents a comparison of the differences in inter-annotator agreement between quality assessments using sentence and document-level set-ups. We report results of the agreement between professional translators for fluency and adequacy scales, error annotation, and pair-wise ranking, along with the effort needed to perform the different tasks. To best of our knowledge, this is the first study of its kind.

1 Introduction

Increasing efforts have been made in order to add discourse into neural machine translation (NMT) systems. However, the results reported for those attempts are somehow limited as the evaluation is still mostly performed at the sentence level, using single references, which are not able to recognise the improvements of those systems. The state-of-the-art automatic evaluation metrics have been shown to underestimate the quality of NMT systems (Shterionov et al., 2018), and the suitability of these metrics for document-level systems has also been criticised (Smith, 2017). For that reason, document-level human evaluation of machine translation (MT) has raised interest in the community recently as it enables the assessment of suprasentential context.

In a survey with native speakers, Castilho et al. (2020) tested the context span for the translation of 300 sentences in three different domains, namely reviews, subtitles, and literature. Over 33% of the sentences tested were found to require more context than the sentence itself to be translated, and from those, 23% required more than two previous sentences to be properly translated. Ambiguity, terminology, and gender agreement were the most common issues found to hinder translation. Moreover, differences in issues and context span were found between domains. This shows that document-level evaluation enables the assessment of textual cohesion and coherence types of errors which are impossible at times to recognise at sentence level.

Recent attempts to assess quality at the document-level were described in Toral et al. (2018) and Läubli et al. (2018) who independently reassessed the bold claims of MT 'achieving human parity' and found that the lack of extra-sentential context has a great effect on quality assessment, and pointed to a failure of the current best practices in MT evaluation. Toral et al. (2018) used consecutive single sentences to rank translations by two MT systems and a human reference. They found that the evaluators were able to better assess the translations when provided with more context, and moreover, inter-annotator agreement (IAA) between professional translators was higher than that between non-experts. However, this methodology does not discriminate sentence vs document-level set up as single sentences are shown consecutively.

Läubli et al. (2018) used pairwise rankings of fluency and adequacy to evaluate the quality of MT vs human translation (HT) for document-level texts. The methodology consists of translators choosing the 'best' translation in terms of i) adequacy and ii) fluency, that is, instead of choosing on a scale on how fluent or adequate the translations are, the raters just choose the 'best' one. Although not reporting IAA in the main paper, the authors report some IAA scores in the appendix of that work, showing that for fluency, document-level set up has

Proceedings of the 5th Conference on Machine Translation (WMT), pages 1150–1159

higher IAA than for sentence set-up, but the opposite for adequacy. However, while this evaluation methodology seems appropriate when comparing different translations, it would not be feasible when evaluating a single MT system.

After these two papers were published, for the first time the WMT19 attempted a document-level human evaluation for the *news* domain. In that year, the direct-assessment (DA) task asked crowdworkers to give a score (0-100) regarding the accuracy of the translated sentence, where only one MT output is shown each time (no comparison with other MT system). However, conventional Kappa cannot be using with DA to measure IAA, and so consistency is measured instead, where raters have to pass some quality control criteria (Barrault et al., 2019).

In light of this, a comparison of IAA between quality assessments on sentence and document-level set-ups is needed in order to determine which set-up results in most reliable evaluation. This study presents a small-scale comparison on the differences in IAA between these two methodologies. To the best of our knowledge, this is the first paper to compare IAA for sentence vs document-level set-ups using the state-of-the-art MT evaluation metrics, namely fluency and adequacy scales,[1] error mark-up and pairwise ranking, along with reporting effort indicators.

We provide a detailed description of the experimental methodology in Section 2. Following, we report results in Section 3 on the agreement between professional translators for fluency and adequacy scales, error annotation, and pair-wise ranking (in 3.1), along with the effort needed to perform the different tasks (in 3.2). We discuss our results and draw conclusions in Section 4, and point out directions for future work.

2 Methodology

Five professional English (EN) to Brazilian Portuguese (PT-BR) translators were hired to perform the evaluation in terms of (1) fluency, adequacy, and error mark-up using the PET tool (Aziz et al., 2012); and (2) pairwise ranking using Google spreadsheet. The choice of PET was due to the fact that the tool is a free toolkit, easy to use, with its UI resembling translation tools, and it is able to handle different evaluations while logging time spent on tasks.

The evaluation was carried out in two scenarios: (A) evaluation at the sentence level, showing randomised sentences, one at a time, one score per sentence, and (B) evaluation at a document level, showing randomised documents, one document at a time, one score per document. After each scenario was complete, translators answered a post-task questionnaire about the evaluation and their perceived effort.

	Test Set 1	Test Set 2
Av. Sentence Length (WPD)	316	344
Av. Sentence Length (WPS)	20	21
Av. Sentence Count (SPD)	15	15
Total Words	10135	11019
Total Sentences	500	500
Total Docs	32	32

Table 1: Statistics for the test sets used, where average sentence length is calculated as words per document - WPD - (scenario B), words per sentence - WPS - (scenario A), and average sentence count is calculated as sentence per document - SPD.

	Test Set 1		Test Set 2	
	Source	Translation	Source	Translation
Flesch	47.9	57	50	55
TTR	0. 26	0.27	0.25	0.27

Table 2: Type-token Ratio (TTR) and Flesch Reading Ease Scores for both source and translated sides of Test Sets.

Corpus - We used the English corpora from WMT `newstest2019`, which has an average document length of 17 sentences (minimum 4 sentences, maximum 30 sentences). In total, 64 full documents were selected (32 per scenario) with 1000 sentences (500 per scenario). We made sure that both scenarios are comparable in terms of sentence and document length, as well as in terms of readability and lexical variation. Results on statistics of both data sets in Table 1, along with results for Type-Token Ratio and Flesch Reading Ease Scores in Table 2 (for both source and translated versions), show that, in fact, both test sets and translations are comparable. This suggests that any variation on the assessments is unlikely to be because the two test sets are overly distinctive.

The corpus was then translated from EN into PT-BR with Google Translate (for adequacy, fluency, and error mark-up) and also with DeepL for the ranking pairwise comparison.[2]

[1] It is important to notice that Läubli et al. (2018) used pairwise ranking of fluency and adequacy instead of the standard Likert scale.

[2] The online translators were used between 20-26 February 2020.

Translators - Five professional translators took part in the evaluation.[3] Their professional experience ranges from 6 to 14 years, and three of them have had previous experience with translation evaluation. A warm-up task with 20 sentences was set up so translators could get acquainted with the tasks, guidelines and tools, as well as clarify any doubts about the task. Each translator evaluated 1000 sentences, 500 in each scenario and Test Set. Table 3 shows the distribution of the task for each translator. No time limit was stipulated for the translators to finish the task, but they were asked to keep track of the time needed to complete the tasks.

Translators	T1,T5	T2	T3	T4
Test Set 1 (1-500 sent.)	S_1	S_2	D_1	D_2
Test Set 2 (501-1000 sent.)	D_2	D_1	S_2	S_1

Table 3: Distribution of tasks where S is sentence level and D is document level scenarios, and 1 and 2 is the order of the tasks.

Post-task Questionnaire - The post-task questionnaire consisted of 10 statements for each scenario, assessed on a scale from 1 to 6, where 1 is a negative answer (strongly disagree/very difficult/very tiring) and 6 is an affirmative answer (strongly agree/very easy/not tiring at all). The statements were the following:

1. I was *always* able to understand the meaning of the source [sentence/texts]
2. I was *always* able to understand the meaning of the translated [single sentence/full texts]
3. I was *always* able to recognise all the problems with the translation of [single sentence/full texts]
4. I would have preferred to evaluate [full texts/single sentences] than [single sentence/full texts]
5. I would have preferred to evaluate pair of sentences than [single sentence/full texts]
6. I would have preferred to evaluate full paragraphs than [single sentence/full texts]
7. I was satisfied with the evaluation I provided for the [single sentence/full texts] job
8. Spotting errors in the each translated [single sentence/full texts] was (difficulty level)
9. Assessing the translation quality on a [single sentence/full texts] level was (difficulty level)
10. Assessing the translation quality on a [single sentence/full level] was (fatigue):

[3] At the time of submission of the paper, we had reported scores from 4 translators (T1, T2, T3 and T4). For the final submission we decided to add a 5th translator to be compared with T1&T2 in order to get a further understanding of issues observed with T1. Therefore, we keep the presentation of the scores between T1&T2 and, following, we present Fleiss Kappa scores with T1&T2&T5 as additional results.

3 Results

3.1 Inter-annotator agreement (IAA)

We compute IAA with Cohen's Kappa (Cohen, 1960) both weighted (W) and non-weighted (NW) as the most common statistics for IAA,

$$k = \frac{P(A) - P(E)}{1 - P(E)}$$

where $P(A)$ represents the proportion of times that the annotators agree, and $P(E)$ the proportion of times that the annotators are expected to agree by chance. While NW Kappa does not take into account the degree of agreement, W Kappa uses a predefined table of weights to measure the degree of disagreement between the two raters, the higher the disagreement the higher the weight. It is important to notice that in this case, W Kappa can only be calculated for adequacy and fluency as they are assessed using a Likert scale.

In addition to that, we also compute Inter-rater reliability (IRR) as the level of agreement between raters (percentage of matches), and Pearson correlation (r) between T1&T2 and T3&T4 (see Table 3). The comparison of the scenarios (sentence *vs* document) is calculated between the Test Sets (Test Set 1 & Test Set 2). We calculate IAA for all the tasks, namely adequacy, fluency, error and ranking. It is important to note that Fleiss Kappa is computed when analysing T1&T2&T5.

Due to the exploratory nature of this research, along with the small number of participants which is known to hinder the effectiveness of statistical analysis, we interpret the results gathered with these evaluations from a qualitative perspective.

3.1.1 Adequacy

Adequacy was assessed for each single sentence and full document (one score per document). Translators answered the question *"How much of the meaning expressed in the source appears in the translation?"* on a Likert scale from 1-4.[4] Table 4 shows the IAA scores for adequacy.

[4] 1. None of it, 2. Little of it, 3. Most of it, 4. All of it

Adequacy		SENTENCE	DOCUMENT
Test Set 1		T1&T2	T3&T4
Kappa	NW	0.13	0.01
	W	0.27	0.23
Pearson		0.5	0.64
p-value		0	0
IRR		47%	44%
Test Set 2		T3&T4	T1&T2
Kappa	NW	0.34	-0.06
	W	0.27	-0.12
Pearson		0.53	-0.37
p-value		0	0.03
IRR		63%	25%

Table 4: IAA for adequacy assessments for single sentences and full texts scenarios.

When looking at Test Set 1 (upper part of the table), we note that both W and NW Kappa show a higher score for single-sentence scenario. Interestingly, the difference between IAA scores for sentence and document for Test Set 2 (lower part) is very discrepant with IAA scores for document level reaching negative levels. This trend is supported by the negative correlation and the low IRR percentages. Since we have demonstrated that both test sets are comparable, we believe that translators T1 and T2 indeed disagreed on adequacy scores for the document scenario more than they did for the sentence scenario.

When adding T5 to the adequacy assessment, we see a decline in Kappa for both sentence-level and document-level scenarios, where k=0.04 and k=-0.12 respectively (Table 5) in contrast to k0.13 and k-0.06 (see Table 4). Conversely, we note an increase in IRR for both sentence and document-level scenarios, where IRR is 67% and 42% respectively (in contrast to 47% and 25%). These results draw near the results from T3&T4. Nevertheless, we note that IAA is higher when evaluations are performed in the sentence-level scenario.

Adequacy	SENTENCE	DOCUMENT
Test Set 1	T1&T2&T5	T3&T4
Kappa	0.04	0.01
IRR	67%	44%
Test Set 2	T3&T4	T1&T2&T5
Kappa	0.34	-0.12
IRR	63%	42%

Table 5: IAA for adequacy assessments for single sentences and full texts scenarios including T5.

3.1.2 Fluency

Fluency was also assessed for each single sentences and full documents (one score per document). Translators answered the question *"How fluent was the translation?"* on a Likert scale from 1-4.[5] Table 6 shows the IAA scores for fluency.

Fluency		SENTENCE	DOCUMENT
Test Set 1		T1&T2	T3&T4
Kappa	NW	0.09	0.41
	W	0.06	0.25
Pearson		0.1	0.73
p-value		0.02	0
IRR		53%	56%
Test Set 2		T3&T4	T1&T2
Kappa	NW	0.27	0.05
	W	0.34	-0.02
Pearson		0.42	-0.11
p-value		0	0.53
IRR		57%	47%

Table 6: IAA for fluency assessments for single sentences and full texts scenarios.

When looking at Test Set 1, we note that IAA is higher in the document-level scenario for both W and NW Kappa when compared to the single-sentence scenario. This is confirmed by the linear relation expressed by Pearson. This might suggest that fluency is easier to assess with full texts rather than with non-contextual sentences. However, the same is not true when looking at Test Set 2, where W Kappa even reaches negative scores in the document-level set-up. Once again, we see that the IAA differences are bigger for T1&T2 who assessed Test Set 1 in the sentence-level scenario and Test Set 2 in the document-level scenario (see more discussion on this in Section 4), which is again confirmed by the negative correlation.

Fluency	SENTENCE	DOCUMENT
Test Set 1	T1&T2&T5	T3&T4
Kappa	0.88	0.41
IRR	63%	56%
Test Set 2	T3&T4	T1&T2&T5
Kappa	0.27	-0.12
IRR	57%	50%

Table 7: IAA for fluency assessment for single sentences and full texts scenarios including T5.

When adding T5 to the fluency assessment, we see a large increase in IAA for sentence-level scenario where k=0.88 and IRR=63% (Table 7) in contrast to k=0.09 and IRR=53% (Table 6). However, we note that apart from a slight increase in IRR for the document-level scenario (50% compare to 47%), Kappa shows a decrease reaching a negative value k=-0.12. With these new results, both

[5] 1. No fluency, 2. Little fluency, 3. Near native, 4. Native

Kappa and IRR are higher when evaluations are performed in the sentence-level scenario. However, by looking at the **translator pair** T3&T4, we can see that these two translators still agreed more when judging the document-level scenario (k=0.41) than when judging the sentence-level scenario (k=0.27).

3.1.3 Error

Error annotation was performed after translators assessed fluency and adequacy. Translators were asked to select from a drop-down menu which errors they found in the MT output. Because we are only interested in the agreement level between translators (as opposed to finding out the quality of the MT system), we decided to use a simple taxonomy that consisted of four error categories: Mistranslation, Untranslated, Word Form, and Word order. Translators could also select "No errors" in case the sentence/document did not contain any error. Each sentence or document could be annotated with more than one error category, but unfortunately because PET does not allow for word-level tagging, each error category could be assigned only once. Therefore, a segment or document could be tagged as containing all the errors, some of the errors, as well as no errors (no issues), but if the translator found that the segment contained *two* mistranslation errors, for example, the mistranslation category would be assigned only once to that segment. Yet again, we believe this set-up is enough to measure agreement levels.

Error mark-up results were divided into *binary*, when raters agree whether there was an error (any type) or no errors in the sentence/document,[6] and *type*, when raters agree on the exact error type found in the sentence/document. Table 8 shows the results for IAA for the error mark-up task.

The error annotation task shows higher IAA and IRR in document-level scenario for Test Set 1, however, the low Pearson correlation score does not indicate a strong linear relation. For Test Set 2, we see that sentence-level scenario shows higher Kappa for error *type* and higher IRR, confirmed with a positive correlation. It is important to note that Kappa for the *binary* classification in the document-level scenario is 1 (marked as n/a) as translators agreed that (almost) all documents contained **at least** one error. However, Kappa penalises it as all the ratings fall into a single category.

[6]Intuitively, one might expect that at least one error will be found in a full document and so IAA will be high for document-level set-up in the binary category.

Error		SENTENCE	DOCUMENT
Test Set 1		T1&T2	T3&T4
Kappa	binary	0.28	n/a
	type	0.22	0.31
Pearson		0.21	0.08
p-value		0	0.49
IRR	binary	60%	100%
	type	50%	53%
Test Set 2		T3&T4	T1&T2
Kappa	binary	0.49	n/a
	type	0.38	0.20
Pearson		0.7	0.08
p-value		0	0.49
IRR	binary	76%	90%
	type	56%	33%

Table 8: IAA for error mark-up for single sentences and full text scenarios.

For this reason, we decided to also compute F-score for absolute error (disagreement) in the *binary* category (see Table 9).

ERROR	SENTENCE	DOCUMENT
Test Set 1	T1&T2	T3&T4
F-SCORE	60.4	100
Test Set 2	T3&T4	T1&T2
F-SCORE	76.6	93.75

Table 9: F-score for *binary* error mark-up evalaution.

F-scores show that indeed, *binary* classification is higher for the document-level scenario since we expect the full text to contain at least one error type. However, it is interesting to note that the document-level scenario for Test Set 2 presents only a 93.75 score and 90% (Table 8) since T1 and T2 disagreed in one document.

Error		SENTENCE	DOCUMENT
Test Set 1		T1&T2&T5	T3&T4
Kappa	binary	0.16	n/a
	type	0.02	0.31
IRR	binary	60%	100%
	type	56%	53%
Test Set 2		T3&T4	T1&T2&T5
Kappa	binary	0.49	-0.07
	type	0.38	-0.02
IRR	binary	76%	88%
	type	56%	50%

Table 10: IAA for error mark-up for single sentences and full text scenarios including T5.

By adding scores from T5 (Table 10), we note that IAA scores for Test Set 1 do not differ much, and document-level scenario shows higher Kappa and IRR as discussed previously. For Test Set 2, IAA scores decrease for Kappa, both for binary and error type categories. Interestingly, IRR scores for

Ranking	SENTENCE	DOCUMENT
Test Set 1	T1&T2	T3&T4
Kappa	0.36	0.22
Pearson	0.41	0.36
p-value	0	0.04
IRR	59%	56%
Test Set 2	T3&T4	T1&T2
Kappa	0.29	0.19
Pearson	0.41	0.42
p-value	0	0.01
IRR	53%	47%

Table 11: IAA for Pair-wise ranking evaluation.

the binary category also slightly decreases. This is a bit surprising as we were expecting translators to assign at least one error type to full texts. The results with T5 indicate that, annotating error at a document-level is difficult as translators cannot tag exactly what the problematic parts are.

3.1.4 Ranking

Pairwise ranking was performed between translation from Google translate and DeepL. The systems' outputs (single sentences in scenario A, and full documents in scenario B) were randomly mixed so translators would see different outputs. Translators were asked to rate their preferred translation, and ties were allowed. Table 11 shows the IAA for the ranking task.

In Test Set 1, the ranking evaluation shows higher IAA for sentence-level scenario when compared to the document-level. Test Set 2 shows document-level scenario with lower agreement as seen in previous trend.

When adding scores from T5, we can see in Table 12 that IRR scores do not change. A 0.1 point decrease in Kappa scores can be observed for Test Set 1 for the sentence-level scenario (k0.36 to k0.26), and a slight decrease in Kappa scores for the document-level scenario fro test Set 2 (k0.19 to k0.14).

Rank	SENTENCE	DOCUMENT
Test Set 1	T1&T2&T5	T3&T4
Kappa	0.26	0.22
IRR	59%	56%
Test Set 2	T3&T4	T1&T2&T5
Kappa	0.29	0.14
IRR	53%	47%

Table 12: IAA for ranking assessment for single sentences and full texts scenarios including T5.

Interestingly, when looking at the output of both systems, Google seem to prefer to drop gender markers more than DeepL, which might make the sentence less adequate in terms of specifying who is speaking but the sentence can still be very fluent.

1) **Source**: *Her* decision to pull out left everyone involved absolutely stunned.
DeepL: A decisão *dela* de se retirar deixou todos os envolvidos absolutamente atordoados.
Google: *Sua* decisão de sair deixou todos os envolvidos absolutamente atordoados.

2) **Source**: To recover *it* is a duty."
DeepL: Recuperá-*lo* é um dever".
Google: Recuperar (x) é um dever."

This might suggest that translators' personal preferences play a role in document-level evaluation as well. For instance, translators might prefer adequacy over fluency, as in example 1, or in the case when there is not enough context in the source to specify the gender or solve ambiguity, translators might prefer the drop of the gender marker (as in example 2).

3.2 Effort

The effort spent on assessing the two scenarios was calculated in two ways: i) time translators spend assessing the sentences and full texts, and ii) self-report of effort required to perform the tasks via a post-task questionnaire.

Time - The time spent on evaluating Adequacy, Fluency and error mark-up could be drawn directly from PET logs. Unfortunately, it was not possible to count time for the ranking task because the pairwise comparison was performed in Google Spreadsheet, and so no automatic log could be drawn. Although they were asked to keep track of their time while ranking the MT output, translators recorded this inconsistently. Therefore, we decide to use only the times logged in PET.

When performing the evaluation in PET, translators first had the chance to see the source and MT side by side in the post-editing window[7] and then to assess the MT output in another window. Therefore, PET logs two different times: one spent in the PE window, and one spent in the assessment window. Intuitively, one would believe that the translators would read the sentences/texts in the PE window and use the evaluation window only to

[7]It is worth noticing that the option of performing PE was disabled, so no time for any changes was counted.

Transl.		Reading	Assessing	Total
T1	Sent.	*09:29:33	*14:16:57	*23:46:30
	Doc	02:51:38	03:14:53	06:06:31
T2	Sent.	02:45:44	08:18:51	11:04:35
	Doc	03:25:39	02:08:26	05:34:05
T3	Sent.	05:42:25	03:07:27	08:49:52
	Doc	02:36:11	00:24:20	03:00:31
T4	Sent.	03:53:21	02:05:25	05:58:46
	Doc	02:41:15	01:13:46	03:55:01
T5	Sent.	00:35:22	05:43:11	6:18:33
	Doc	00:11:43	01:29:46	1:41:29

Table 13: Time spent on performing fluency, adequacy and error mark-up assessments in PET tool. (Note that T1 *times are compromised.)

give the scores. However, it is possible that some translators might have taken some time to read the source and MT in the assessment window.[8] Moreover, T1 reported that for the document-level scenario, they sometimes took a screenshot of the PE window "when the text was too long" and used it while evaluating the text in the assessment window (since the full text is not completely displayed in the PET assessment window).

For that reason, we decided to show both reading time (time spent on the PE window) and assessment time (time spent on the assessment window), and the total spent time. Table 13 shows the times spent for the task.

Unfortunately, T1 reported difficulties in carrying out the evaluation (due to COVID-19) and self-reported he was distracted while doing it, leaving the tool running mid-evaluation. For this reason, even when discarding obvious outlier times, there is a great discrepancy in the amount of time for T1 compared to the other translators: while translators had an average of 7-9 hours to complete the tasks, T1 took 23 hours to complete the task. Consequently, we decided to repeat T1's evaluation with T5 in order to see if patterns could be drawn from time spent on tasks.

Intuitively, one would expect translators to spend longer reading time for the document-level scenario compared to the sentence-level one, since full texts are longer. Furthermore, one would expect the assessing time to be longer for the sentence-level scenario since each sentence requires one assessment (500 assessments for 500 sentences), while in the document-level scenario, each text is assessed just once (32 assessments for 500 sentences). However, while T2 and T3 show longer reading time for document-level scenario, T1, T4 and T5 show lower reading time for that scenario.

Even though results for time do not seem to be a strong indicator of effort due to the PET's user interface limitation, it is interesting to note that while some translators do spend more time reading, some spend more time assessing. This might indicate that having the text available during the assessment of fluency/adequacy is essential for translators.

Post-Task Questionnaire - Translators answered the post-task questionnaire (see full statements in Section 2) after they finished all tasks in both scenarios. Table 14 show the average results for each statement (including T5's responses).

Statements	Sent.	Docs
1- understand source	5	5.4
2- understand translation	4.2	3.8
3- recognise problems	5.2	4.8
4- prefer (docs/single sent.) than (single sent./docs)	4	4.6
5- prefer pair of sentences than...	3.8	5
6- prefer full paragraphs than...	3.6	4.2
7- satisfied with evaluation	4.8	5
8- Spotting errors was (very easy - very difficult)	5.2	4.4
9- Assessing was (very easy - very difficult)	4.6	4.2
10- Assessing was (very tiring- not tiring)	3.2	1.8

Table 14: Post-questionnaire results (average). Scale range from 1 to 6 where 1 is strongly disagree/very difficult/very tiring and 6 is strongly agree/very easy/not tiring at all.

We observe a few interesting results for statements 1 and 2, where translators seem to be able to understand the meaning of the source better in the document-level scenario, but the meaning of the translation better in the sentence-level scenario. More interestingly, the average for statement 3 is slightly lower for document-level which might suggest that translators were less able to recognise all problems with the translation in the document-level scenario, likely due to the number of sentences.

Translators seem to prefer to judge single-sentences than full documents (statement 4), and, would rather evaluate sentence pairs (statement 5) or paragraphs (statement 6) than full documents.

Nevertheless, results for statements 8 indicate that translators found easier to spot errors in the full texts (which contradicts the results for statement 3). Previous work on evaluation of NMT systems (when compared to SMT) found translators find

[8] PET displays the MT and Source at the top of the assessment window.

NMT errors more difficult to identify due to its high fluency (Castilho et al., 2017) (at a sentence-level). This could be a good indication that, due to good levels of fluency in NMT systems, indeed the exhibition of full texts is more helpful for the assessment in general.

Finally, translators found the document-level scenario to be slightly easier to assess (statement 9) but much more tiring than assessing single sentences (statement 10).

4 Discussion

This paper attempts to shed light on the differences in IAA between sentence and document-level evaluation scenarios. The experiments performed with five professional translators have tested the state-of-the-art metrics commonly used to assess MT quality with humans, namely the assessment of fluency, adequacy, error mark-up and pairwise ranking (Castilho et al., 2018).

We note that when evaluating *adequacy* (Table 4) the scenario where single sentences are assessed show higher IAA for both test sets, and moreover, IAA for Test Set 2 presents the lowest IAA for the document-level scenario for all the metrics. Regarding *fluency* assessment (Table 6), document-level scenario for Test Set 1 has higher IAA but Test Set 2 the opposite is seen for Test Set 2.

In addition to scores per test sets, it is interesting also to look at the IAA scores by **translator pairs**. We observe that there is a large difference between T1&T2 who evaluated Test Set 1 in the sentence-level scenario, and Test Set 2 in document-level scenario, against T3&T4 who evaluated the opposite. T1 and T2 tend to disagree more in both Test Sets for both fluency and adequacy assessments, while T3&T4 have closer IAA scores and higher Pearson correlation. The addition of T5's assessments, reported in terms of Fleiss kappa, indicate that for the majority of the case, IAA is indeed higher when evaluation is performed at a sentence level.

Figure 1 shows examples of disagreement between translators. In example (1), T1 assessed the text as containing "little" of the meaning of the source, T2 considered it to contain "all of it", and T5 assessed it as containing "most of it" (*adequacy*). T1 comments that "many mistranslations of golf/sport terms impaired meaning" and "some unstranslated terms found ('team USA', 'singles')", while T2 thinks that the text contains "minor issues, but the meaning isn't lost", and T5 says "the meaning is compromised by the word-by-word translation". While both T1&T2 agree that the text is "near native" regarding *fluency*, T5 assess it as having "little fluency", mentioning that fluency is also "compromised by the literal translation of some terms".

For T3&T4, the disagreement in the document-level (example (2)) is not as strong. While T3 assesses it as containing "most of the meaning", T4 thinks that it contains "little of it" because "there are a couple of plays on words in the source text, a big part of the translation is lost". However both agreed that regarding fluency, example (2) has "little fluency".

We speculate that the disagreements at the document-level scenario, especially for the adequacy evaluation, might be connected to the fact that because the texts are made up of "very good", "reasonably" and "poorly" translated sentences which, together, make the text understandable to a certain level, it is harder for translators to be consistent when assigning one single score for a full text. We estimate the percentages of *adequacy* scores for the document-level scenario as follows: T1&T2&T5 show 0% for score 1 (none of it), 7.29% for score 2, 61.46% for score 3, and 31.25% for score 4 (most of it); while T3&T4 show 4.69% for score 1, 17.19% for score 2, 64.06% for score 3, and 14.06% for score 4. These results show that a great number of scores fall into the middle category which makes it difficult for a consistent evaluation on a document-level scenario. Consequently, this type of problem will be persistent when evaluating at a document-level MT systems that operates at the sentence level, because a document translated with sentence-level NMT is still a sequence of translated sentences rather than an entire document translation.

We observe that disagreements in the sentence-level are more often related to ambiguity and lack of context. In example (3), while T1 commented that the translation "failed to use football terminology" and assessed it as containing "none of the meaning", T4 and T5 assessed it as containing "all of the meaning". We speculate that T4 and T5 were unaware that the sentence was about football due to the lack of context, and did not penalise mistranslations such as 'fired' which is better translated as 'chutar' (to kick) and 'box' which should be translated as 'pequena área'. T5 even mentioned that

(1)	Ryder Cup 2018: Team USA show stomach for fight to keep hopes alive heading into Sunday singles. After three one-sided sessions, Saturday afternoon's foursomes might just have been what this Ryder Cup needed. (3)	He then fired a beautiful through ball, leading Hazard into the box.	Ele então disparou uma bela bola cruzada, levando Hazard para dentro da caixa
(4)	It would see employees enjoy a three-day weekend - but still take home the same pay.	Veria que os funcionários desfrutariam de um fim de semana de três dias - mas ainda levariam para casa o mesmo salário.

Figure 1: Examples of disagreement between translators.

they had problems with the word "Hazard" because eve thought "it seems to be a noun as it starts with a capital letter, I could not assess whether "Hazard" is a proper noun or just a noun, due to lack of context".

Example (4) is another example of lack of context, since the pronoun "It" is impossible to identify in the sentence. While T3 decides to rely only on the context given and assess *adequacy* as "all of it" and *fluency* as "native", T4 assesses the sentence as containing "little of the meaning" and "little fluency". According to T4, "the context was not enough to translate the pronoun 'it'". This is consistent with findings in Castilho et al. (2020) where authors found that over 33% of the surveyed sentences required more context than the sentence itself to be translated. Indeed, with the context of previous sentences it is possible to identify that "it" relates to "a radical plan" and therefore the addition of "O plano veria" (the plan would see) in the translation would make it more adequate:

(+2) Jeremy Corbyn's Labour Party is to consider **a radical plan** which will see Britons working a four day week - but getting paid for five.

(+1) The party reportedly wants company bosses to pass on savings made through the artificial intelligence (AI) revolution to workers by giving them an extra day off.

(S) ***It*** *would see employees enjoy a three-day weekend - but still take home the same pay.*

Interestingly, T1, T2 and T5 who assessed this sentence in context in the document-level scenario agreed that the text was "near native" and contained "most" and "all" of the meaning. This might be another indication that fluency is better assessed at a document level.

Regarding error mark-up assessment (Table 8), even though for Test Set 1 the document-level scenario has higher IAA than the sentence-level scenario, we note that when looking at **translator pairs**, the document-level scenarios has lower IAA scores for both test sets. Looking at T3&T4 both translators agree more on the error *types* found in the sentence-level than on the document-level scenario.

Finally regarding effort, unfortunately the logged time in PET tool was not decisive, even witht he addition of T5's assessments (due to discrepant results by T1 (Table 13)). Nevertheless, we believe that the results reported here show how difficult it is to run human evaluations, especially unsupervised ones. Additionally, the lack of proper tool able to handle different MT evaluation methodologies makes the assessment even more complex. We consider that time log gathered in PET can still be useful to draw specifications to develop a MT evaluation tool able to handle different methodologies. With respect to translators' self-assessment of their effort, the results from the post-task questionnaire showed that while translators prefer to see full texts than single sentences, they would rather see sentence pairs and paragraphs than having to assess full documents. This is not surprising since evaluating at a sentence-level is is what translators are used to already. Furthermore, they find assessing a full document more tiring than the alternative.

5 Conclusions and Future Work

The present work attempts to shed light at the differences in IAA when evaluating MT at the sentence and document levels with a small scale comparison. The main key findings of this comparison is that, a document-level evaluation methodology where translators assign one score per text leads to lower levels of IAA for adequacy, ranking, and error mark-up (when compared to methodologies where translators assign one score per sentence), but it might be useful for fluency assessments. This

is consistent with (Läubli et al., 2018) findings on IAA for pairwise comparison, and previous work on NMT evaluation, where fluency proved to be harder to assess (than adequacy) in sentence-level scenarios.

Nevertheless, we also speculate that as Google Translate seems to operate on a sentence-level, a document-level evaluation of adequacy is penalised since a document can be constituted of sentences with different levels of quality. Moreover, we consider whether multiple scores per document (sentence pairs, paragraphs, and word-level error tagging) will yield higher levels of IAA when compared to the randomised sentence-level set-up for both sentence and document-levels MT systems.

Human-evaluation of MT in document-level set-ups is in its infancy, and therefore, it is essential to test which methodologies will be best suited for different tasks and domains. Future work will use more translators and different methodologies, as expressed in the post-task questionnaire and discussed above, with more specific guidelines for context-span issues found in previous works, and the development of test-sets, as well as using document-level MT systems' outputs.

Acknowledgments

I would like to thank the translators who participated in the experiment. Also a big thank you to Maja Popović and Joss Moorkens for the brainstorming sessions. This project was funded by the European Association for Machine Translation through its 2020 sponsorship of activities programme. The ADAPT Centre for Digital Content Technology (www.adaptcentre.ie) at Dublin City University is funded by the Science Foundation Ireland Research Centres Programme (Grant 13/RC/2106) and is co-funded by the European Regional Development Fund.

How Should Markup Tags Be Translated?

Abstract

The ability of machine translation (MT) models to correctly place markup is crucial to generating high-quality translations of formatted input. This paper compares two commonly used methods of representing markup tags and tests the ability of MT models to learn tag placement via training data augmentation. We study the interactions of tag representation, data augmentation size, tag complexity, and language pair to show the drawbacks and benefits of each method. We construct and release new test sets containing tagged data for three language pairs of varying difficulty.

1 Introduction

The quality of machine translation (MT) has drastically improved in recent years, making MT technology more widely used than ever before in applications ranging from financial services (Nunziatini, 2019) to fashion, social media, and other user-generated content (Kosmaczewska and Train, 2019; Birch et al., 2019; Michel and Neubig, 2018), among other tasks.

A large amount of content requiring translation is not isolated plain text. Rather, it originates in the context of structured documents, using document format specifications such as HTML, Microsoft Word, PDF, etc.

Currently, the translation industry addresses the translation of structured documents by dividing the task between a translation management system (TMS) and an underlying MT system (e.g. Federico et al. (2014)). Figure 1 shows a schematic of the process. The TMS parses, manipulates, and validates the higher-level document structure. It is responsible for finding the translatable portions of the input document, performing sentence segmentation on the content, sending it to an underlying MT system for translation, and placing the result back into the document structure. For example, the TMS may pass over material contained in HTML `<script>...</script>` tags, while sending to MT the contents of `<p>...</p>` tags and the string values of `<img alt="..."/>` attributes.

Properly transferring formatting tags *within* the translatable content (bold, italic, hyperlink, superscript, etc.) remains the responsibility of the MT process rather than the TMS. The correct preservation and transfer of inline markup from source to target thus forms a crucial component of the overall quality of the MT system. An accurate placement within the segment of inline markup provides a more readable and usable document in its raw MT form, in addition to saving human time and effort if post-editing is used.

Despite the key role of the MT system in processing structured documents — both in terms of TMS expectations and in lowering translation costs — the setup of translation in the context of structure is rarely addressed in the standard MT evaluation benchmarks. They typically focus on the pure-content, string-based tasks (Joanis et al., 2013; Müller, 2017).

In this paper, we study the question of how inline markup should be represented in and processed by the MT system in order to result in the highest placement accuracy. Given the deep semantic representations and generalization abilities provided by modern neural MT systems, we design a series of experiments to test their capabilities specifically on the problem of markup transfer within the translation process. The paper makes the following contributions:

(1) We propose a technique to augment any parallel corpus with inline tags, addressing the scarcity of high-quality parallel data containing markup tags (Section 3). We show that the method results in highly accurate tag placement and can improve the accuracy of tag placement of MT models when used to augment the training data.

Proceedings of the 5th Conference on Machine Translation (WMT), pages 1160–1173
Online, November 19–20, 2020.

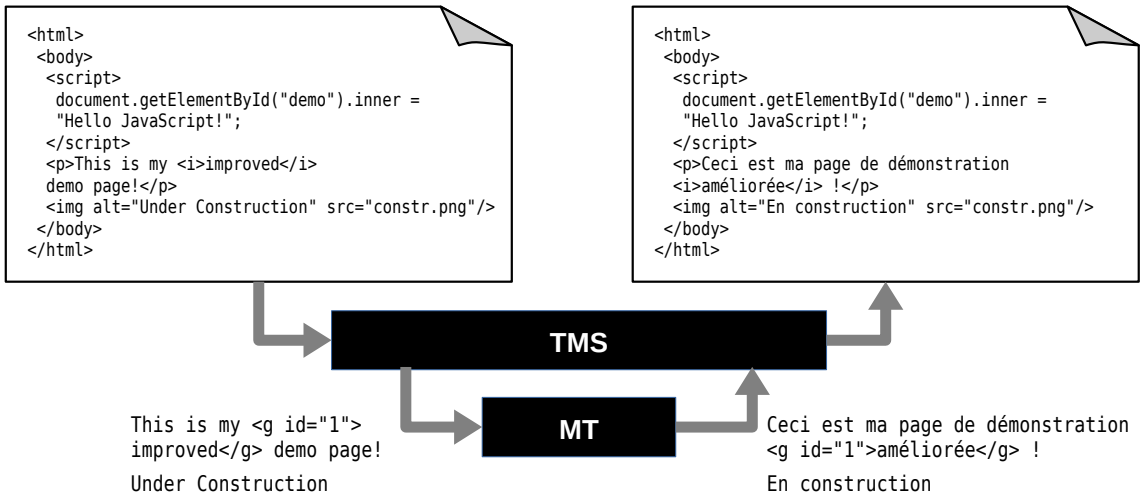

Figure 1: Translation of a structured document. A translation management system (TMS) is responsible for higher-level document structure, while the machine translation (MT) system transfers inline markup.

(2) We provide a comprehensive evaluation of several tag-handling methods (Section 4). We test the ability of neural networks to jointly learn to translate content and transfer tags from automatically generated tagged data. Within this approach, we experiment with two ways of representing tags and compare these with a baseline detag-and-project method, on language pairs of varying data sizes and difficulty (English–French, English–German, and English–Hungarian).

(3) Finally, testing of tag placement accuracy poses difficulties in terms of both data-set availability and quality metrics. For this reason, we assemble new test sets of natively tagged structured documents for the three targeted language pairs. We enhance these test sets by adding synthetically generated tagged data according to human-quality glossary entries (Section 5), and we release these test sets in order to facilitate further research on the topic. Evaluation is carried out according to standard automatic metrics, automatic detection of obvious tagging errors, and human assessments of tag placement accuracy (Section 6).

2 Related Work

Various works have addressed the inline markup problem in the context of statistical MT systems. Joanis et al. (2013) extensively summarize many such methods. Their "two-stream" approach is quite similar to our detag-and-project baseline, relying on phrase and word alignments and carefully designed tag transfer rules to re-insert inline markup into the translated content. Though the accuracy of this approach is tested in a small human evaluation, it is explicitly not compared to any other method of tag representation.

Müller (2017) addresses the same question, comparing five different varieties of detag-and-project and mask-based approaches. The work concludes that the detag-and-project approach of Joanis et al. (2013) performs the best in complicated tagging scenarios, while masking can be a strong approach in simplistic cases.

Moving to neural MT, Hashimoto et al. (2019) experiment with "raw" tags that are left unmodified in the input. The authors test a constrained beam search that restricts the decoder to outputting all and only the tags actually present in the source while maintaining XML well-formedness. They also introduce a pointer mechanism (See et al., 2017) to promote copy-through of tags and other non-translatable content. These restrictions are shown to improve output, but no other tag representation aside from raw tags is tested.

We thus position our work as spanning and unifying elements of these previous studies, directly comparing the major tag representation methods with a minimum of other modeling changes in a state-of-the-art neural MT setting. Additionally we introduce a data augmentation technique that removes the dependence on pre-existing tagged training data assumed by the approaches proposed by e.g. Hashimoto et al. (2019).

In this context, we also note complementary work on the implicit learning of structure by sequence-to-sequence models. Target-side struc-

ture expressed as content, without special annotations, has been used in string-to-tree syntax-based MT by Nădejde et al. (2017) and Aharoni and Goldberg (2017); the latter group notes that well-formed parse trees are generated 99.5% of the time. The masking method of passing abstracted information between input and output has been applied in MT to non-translatables such as numbers, URLs, named entities, etc. (Crego et al., 2016; Post et al., 2019). It has been shown to improve automatic metric scores, with the masks correctly appearing in the MT output a very high percentage of the time (Murakami et al., 2019; Bérard et al., 2019). Source factors, or additional input streams provided in lockstep with the content to translate (Sennrich and Haddow, 2016), are one mechanism for signaling structural information in the input while leaving it accessible to the model. It has been used to augment an MT system with terminology constraints (Dinu et al., 2019), and the same mechanism could be in principle applied to tags as well.

Training data augmentation is a popular way to increase model learning and robustness for specific phenomena. Of particular interest is the finding by Karpukhin et al. (2019) showing that a "balanced diet" of training data synthetically augmented with spelling errors improved model performance on natural errors, without harming performance on clean text. Our notion regarding synthetically injected and naturally occurring tags is similar.

3 Data Augmentation via Tag Injection

The vast majority of data available for MT research appears as plain text only.[1] While tagged training corpora, when available, will inevitably be limited in size, domains covered, and language availability, we propose as an alternative a general technique for injecting markup tags of controlled complexity into any parallel corpus with high accuracy.

Although not always adhering to the strict syntax of a well-defined markup language, most inline tags follow the XML standard and create a hierarchical structure within a segment by introducing either paired tags (opening and closing) or self-closing unary tags. This structure is expected to be preserved by the translation, with paired tags surrounding corresponding text fragments. In Figure 1, the italicized fragment *improved* transfers to italicized *améliorée*. We propose a method to identify such corresponding fragments in the source and target sides of parallel data and to automatically inject tags based on them.

3.1 Tag Injection

We identify corresponding fragments using the hypothesis that, if the out-of-context translation of a sentence fragment is found in the target sentence, then those text fragments are aligned. More formally, assume source segment s and target segment t are each decomposed in three substrings $(s,\ t) = (a\ b\ c,\ x\ y\ z)$, where b and y are not empty. We hypothesize that if an MT model translates b into y in isolation, then b and y are corresponding fragments and we can inject the following tag structure:

$$a\ \texttt{<t>}b\texttt{</t>}\ c$$
$$x\ \texttt{<t>}y\texttt{</t>}\ z$$

In our implementation, the search over candidate n-grams b proceeds in random order, subject to a parameter controlling the maximum span. Our preliminary experiments showed that natively tagged text is not always well-formed. For this reason we introduce a "pair damage fraction" parameter, which sets the probability that one half of the injected tag pair will be skipped. This produces the patterns a <t>$b\ c$ or $a\ b$</t> c, with analogous results on the target side. We also incorporate a fixed probability that the tag will be injected as self-closing rather than a pair, i.e. as a <t/>$b\ c$ or $a\ b$<t/> c. Finally, we allow for the injection of multiple tags into the same parallel segment via a parameter that specifies the maximum number of tag pairs to insert per segment.

This method can be adapted to any markup schema choice. For the experiments described in this paper, we choose XLIFF, a translation industry standard that uses a reduced vocabulary of tag and attribute names as an abstraction over an original document's markup language. We inject four tags in accordance with the XLIFF 1.2 specification:[2] <g>...</g> for a paired tag, <x/> for a self-closing tag, <bx/> for a tag that opens without closing, and <ex/> for a tag that closes without opening. In all cases we include a numerical id attribute, with the value starting at 1 for the leftmost tag injected in each source segment and incrementing by one for each successive tag in left-to-right

[1] A recent exception is the 17-language XML-tagged parallel corpus described by Hashimoto et al. (2019), released publicly in July 2020 concurrently with our work.

source order.

Tag injection may fail in specific instances for several reasons, such as inability to find a (b, y) pair, or matched phrases overlapping with each other and blocking intended injections. We do not explicitly remove or attempt to repair any of these cases, using them instead as additional sources of variety and noise in the final tag-injected corpus.

3.2 Injection Evaluation

We test our hypothesis that the proposed procedure leads to accurate data by performing a human evaluation on the accuracy of tag placement. This experiment is carried out on a random selection of 200 sentence pairs from our training data in each of three language pairs used in our subsequent experiments: English–German (EN–DE), English–French (EN–FR), and English–Hungarian (EN–HU). (See Section 5.1 for details on the training data itself.)

We ask bilingual speakers in the relevant languages to judge whether each individual tag is correctly placed in the output, incorrectly placed (and a proper location for it can be identified), impossible to place (because no correct location exists given the target content), or too unclear to evaluate (e.g. because a placement decision depends on the semantics of the tag). Each set of sentences is independently evaluated by three different people who are not aware of how the tagged data was created.

The results of the evaluation (Table 1) show that the tag injection is accurate: using all the judgements combined, tags are correctly placed in 93.1% of cases in EN–DE, 90.2% in EN–FR, and 86.3% in EN–HU. The rates of actually wrongly placed tags are 3.5%, 5.8%, and 6.1%, respectively, with the remaining tags being judged as impossible to place or as unclear.

Pairwise inter-annotator agreement varies: judges clearly disagree (correct vs. incorrect) no more than 2.3% of the time in EN–DE and EN–FR, though up to 5.9% in EN–HU. Because of the large class imbalance, we also examine Fleiss's κ metric with all three annotators. The overall κ scores are 0.69 for EN–DE and 0.72 for EN–FR, but only 0.39 for EN–HU. In Hungarian, a larger number of tags are judged as correctly placed by one annotator but impossible to place by another, underscoring the difficulty of markup transfer between morphologically and grammatically distant languages.

4 Tag Representations

4.1 Baseline: Detag/Project

Our baseline setup does not model inline tags in any way. Instead, all markup is removed from the run-time input and reinserted into the MT output by a post-processing step. Reinsertion is carried out via *tag projection*: it uses the position of a tag in the input, a subword-level alignment model between source and target, and a set of projection heuristics to determine the analogous position of the tag in the MT output.

The necessary alignment model is built from the MT system's own training data. We use BPE (Sennrich et al., 2016) for subword creation and FastAlign (Dyer et al., 2013) for training the alignment model. At run time, we force-align the detagged BPE-level MT input to the BPE-level MT output, then convert the source-side subword indexes back to their token-level equivalents.[3] This provides a mapping between input tokens and output BPE pieces. A tag or tag pair is transferred from input to output according to this map and several hard-coded rules. Let s_i and t_i represent the ith source token or target BPE piece, respectively, in a segment of length I and J, and let $A(s_i) = \{j\}$ be the set of target indexes j of alignments induced for s_i. Then the most important projection rules are:

- A tag pair <x>...</x> spanning $s_a ... s_b$ encompasses alignments $\ell = \bigcup_{i=a}^{b} A(s_i)$ and is projected to span $t_{\min(\ell)} ... t_{\max(\ell)}$.
- A self-closing tag <x/> appearing before s_a follows alignments $\ell = A(s_a)$ and is projected to appear before $t_{\min(\ell)}$.

[3] An alternative is building and applying the alignment model on tokens instead of BPE pieces. As a practical concern, we prefer the BPE level for ease in handling non-whitespace languages and for its substantially smaller model size.

Figure 2: Example of inline markup tag representation when it is included in the MT input, either by masking or in raw form.

- A tag pair with zero span or a self-closing tag appearing before s_0 is projected to appear before t_0. The same appearing after s_I is projected to appear after t_J.

Additional heuristics specify behavior for cases when the relevant alignment set is empty, when the nesting of the input tags is malformed, when an unpaired tag <x> or </x> appears without its other half, etc.

4.2 Masked and Raw Representations

We compare the above approach to two alternatives where some representation of inline markup is provided to the MT system. Tags are either masked to generic placeholder tokens or else left raw in the input. Figure 2 gives an example of each.

Aside from reducing vocabulary, masking protects the original content from subword splits and mutilations during the MT process. In our implementation, if a mask is present in the source but fails to appear in the MT output, we forcibly add it back at the end of the output; spuriously generated masks are likewise removed. We use a different placeholder name for each of the five XLIFF tag names present in our data; this treats <g> and </g> independently. We also include a sequence number in the mask token, so that the original content can be matched with the correct placeholder in the target side. Similar to the XLIFF `id` parameter, these sequence numbers start with 1 in each sentence pair and increase left to right in the source sentence. Unlike in XLIFF, our placeholder sequence numbers are incremented individually for each of the five placeholder names.

Our other alternative approach leaves the XLIFF tags raw in the input, trusting the MT system to learn their correct formatting as well as placement.

Both the masking and the raw approach rely on tags appearing often enough in the training data — not only for the MT system to learn their transfer and placement, but also to be recognized as tokens as part of the system's subword vocabulary. Since the masks are single tokens, adding self-translating examples as additional parallel data and exempting the mask tokens from BPE application is sufficient. For the raw approach, we include the same number of self-translation examples to boost the frequency count of XLIFF tag tokens above the minimum BPE frequency cutoff. As Figure 2 illustrates, however, this does not necessarily ensure that all possible tag tokens appear often enough in the training data to be recombined by BPE into full tokens: lower-numbered tags still occur more frequently than higher-numbered examples.

5 Experimental Setup

5.1 Training Data

Our training data is sourced from the Conference on Machine Translation (WMT) series of shared tasks. Since our focus is on inline tag handling rather than corpus filtering or new state-of-the-art translation quality, in some cases we have ignored especially large or noisy data sets.

For EN–DE, we begin with the training data released by the WMT 2020 news task, ignoring the Common Crawl and Paracrawl corpora and heavily filtering WikiMatrix. Our EN–FR training data comes from the 2014 news translation task; we use only Europarl, News Commentary, and UN Docs. For EN–HU, we use the single available training corpus from the 2009 translation task.[4] Our final training data comprises 5.7 million lines for EN–DE, 14.5 million lines for EN–FR, and 1.5 million

[4]Data available from http://www.statmt.org/wmt20/translation-task.html (EN–DE), http://www.statmt.org/wmt14/translation-task.html (EN–FR), and http://www.statmt.org/wmt09/translation-task.html (EN–HU).

lines for EN–HU. See Appendix A for the exact enumeration of component corpora, line counts, and a description of our filtering process.

On top of this baseline data, we experiment with various amounts of tag-injected data augmentation. We sample 1%, 2%, 5%, 10%, or 15% of the baseline training data and inject XLIFF tags into it as described in Section 3. We attempt to inject up to two pairs of tags per segment, with a max span of six tokens, pair damage fraction of 0.10, and self-closing fraction of 0.27. Candidate n-grams for tag injection are identified by looking for equivalent translations with the publicly available version of Amazon Translate as of April 2020. Lines that completely fail tag injection are discarded, not counted as part of the goal percentage, and replaced with successful lines. Each successive augmentation percentage is a strict superset of the ones before it: e.g. all the data present in the 2% corpus is also present in the 5%, 10%, and 15% settings.

5.2 Tagged Dev and Test Sets

Although we believe the tag injection technique achieves sufficiently high accuracy to be used in training data, we prefer our development and test sets to represent — as much as possible — naturally occurring tags in the source and human-quality placements for them in the target. This section describes the test sets created. They are also publicly available at https://github.com/amazon-research/mt-markup-tags.

EUR-Lex EUR-Lex[5] is the European Union's online repository of legal documents, which are provided synchronously in several structured formats and in the union's 24 official languages. We select a cohesive block of documents in Microsoft Word format, from CELEX numbers 52019DC0601 through 52019DC0680, to serve as the base of our dev and test sets. Each document is available as monolingual downloads in English, German, French, or Hungarian; several processing steps are needed to create a sentence-aligned tagged parallel corpus.

For a set of four monolingual documents, we first extract each one from Word to XLIFF format using the open-source Okapi Tikal document filter.[6] Aside from performing automatic paragraph and sentence segmentation according to pre-defined rules, the Okapi filter also converts the inline Microsoft markup to XLIFF 1.2 tags. We then check the extracted XLIFF documents for parallelism at several levels. Any document set that does not contain the same number of paragraphs across all four languages is entirely rejected. Any paragraph that does not have the same number of sentences across languages is skipped; any sentence that does not have the same set of XLIFF tags across all languages is likewise skipped. The surviving sentences form a four-way parallel corpus with inline markup tags. Each successfully extracted document is then assigned to either the dev or the test set. Sets assembled in this way are finally deduplicated to unique sentence pairs. The EUR-Lex dev set contains 1888 lines; the test set 1450.

We find, surprisingly, that a significant number of otherwise parallel segments do not contain the same inline tags across all languages. One side effect of enforcing this restriction is that the tags that are indeed parallel are biased towards trivial cases, such as an opening tag at the beginning of the sentence and a closing tag at the end. Only 11% of the sentences extracted above contain line-medial tags, and only 4% contain more than two tags per line. We mitigate this problem via the construction of two additional sets.

EUR-Lex mono We return to the unfiltered monolingual English documents assigned to the EUR-Lex test set. Without parallelism restrictions, this collection forms a much more diverse test set: after deduplication, 26% of lines contain medial tags and 13% hold more than two tags. While we are unable to use this for MT evaluation metrics that require a reference, we employ this 2525-line test set for other types of automatic and human evaluation.

Glossary We use additional EUR-Lex documents (CELEX numbers 52019DC0520 to 52019DC0599) to construct dev and test sets with synthetically introduced tags. In contrast to tag injection, however, the markup is inserted using human-curated translation glossaries. We extract and filter each set of monolingual Word documents as before, with the additional step of removing all the inline tags to obtain plain text. Given four-way parallel segments, we then search within each line for a synchronous occurrence of entries from our glossaries for EN–DE, EN–FR, and EN–HU. If

[5] https://eur-lex.europa.eu/homepage.html

[6] https://okapiframework.org/wiki/index.php/Tikal

found, the terms are surrounded by a pair of identical XLIFF <g>...</g> tags in each language. The synchronous glossary restriction reduces heavily the amount of successfully extracted and tagged sentences. On the other hand, it provides in practice 100% examples with line-medial tags, as well as an improved 22% of lines containing more than two tags. The final sizes are 286 lines for dev and 289 for test.

The complete dev set for our MT systems is a concatenation of three different sources. First is the official WMT dev set that corresponds to the training data: newstest2018 for EN–DE, newstest-2013 for EN–FR, and newsdev2009 for EN–HU. To this we add the EUR-Lex and glossary dev sets described above. Tags are removed from these sets when they are used in the baseline system, which is not trained on any tagged data. Test sets are kept separated by data source. In addition to tagged and detagged versions of the EUR-Lex and glossary test sets described above, we include the EUR-Lex mono test set and the WMT official test sets: newstest2019 for EN–DE, newstest2014 for EN–FR, and newstest2009 for EN–HU. See Appendix A for the complete itemization of dev and test sets.

5.3 MT Systems

All our experiments are carried out using the Sockeye neural MT toolkit (Hieber et al., 2017). We use the Transformer architecture (Vaswani et al., 2017), with a hidden layer size of 512, an encoder of 20 layers, and a decoder of 2 layers: Hieber et al. (2020) report improved WMT results for such a configuration. For training, we set the batch size to 8192 tokens and the checkpoint interval to 2000 batches. Optimization is carried out with Sockeye's implementation of the Adam algorithm (Kingma and Ba, 2014). The learning rate, from an initial value of 0.0002, is multiplied by a factor of 0.9 every time eight training checkpoints pass without any improvement in dev-set perplexity. Training is stopped when there is no improvement after 32 checkpoints. Following convergence, the parameters from the eight best checkpoints are averaged.

We present a total of 33 experimental configurations: the detag-and-project baseline, plus the cross product of {1, 2, 5, 10, 15}% tag-injected data augmentation with {masked, raw} tag representation, for each of our three language pairs.

6 Results

6.1 Evaluation Metrics

Depending on the test set, we use a variety of evaluation metrics to judge performance.

We compute case-sensitive BLEU scores according to the SacreBLEU implementation (Post, 2018).[7] We distinguish untagged BLEU scores computed on test sets with no source-side tags (or for which the source-side tags have been removed) from tagged BLEU scores, where the tags are tokenized and treated as content by the built-in SacreBLEU tokenizer. Evaluation occurs only after any masked placeholders have been converted back to literal output. For each system, we also compute statistical significance relative to the baseline using stratified approximate randomization (Yeh, 2000).

Tagged test sets are also evaluated according to specifically designed "flagrant failure" metrics, whose goal is to detect obviously erroneous tag placement in MT output. Automatic evaluation of tag placement becomes difficult as the MT output diverges from a tagged reference translation's word choice, sentence structure, etc. Still, certain errors can be reliably detected regardless of language or context. We define flagrant-failure metrics to count occurrences of dropped, added, or mutilated tags, along with tags that become improperly nested relative to the source. In XLIFF, we distinguish a change of index — from e.g. <g id="2"> to <g id="4"> — as its own type of failure, rather than as independent drop and add mistakes.

Finally, we conduct a full human evaluation of tag placement accuracy, similar to the one introduced in Section 3.2. Due to the large amount of data involved, in this case we collect judgements from only a single annotator. Each tag is evaluated independently for whether its placement in the target is correct, incorrect, impossible given the MT output, missing, duplicated, or unclear.

6.2 Evaluation of Untagged Input

Our first concern is to ensure that augmenting the training data with tag-injected content does not harm translation of untagged inputs. We validate this claim on untagged versions of our WMT, EUR-Lex, and glossary test sets, comparing the BLEU scores of the tag-augmented systems with the score of the baseline, which was trained without tags.

Raw 1%	183,475
Raw 15%	2,606,016

	`<g id="@@ 3">`	
Raw 1%	183,475	3,150	1,300
Raw 15%	2,606,016	2,550	1,300

Figure 3: Training-data token frequencies for the BPE pieces involved in EN–FR translation of two tags. Indexes above 2 are seldom seen.

As hoped, we observe no clear pattern of degradation by tag representation, augmentation percentage, or language pair. Out of the 90 experimental cases, only four reach statistical difference with the corresponding baseline at $p < 0.05$. These scattered instances are shown in Table 2. See Appendix B for the full results.

6.3 Automatic Evaluation of Tag Placement

We have two proxy metrics at our disposal for automatically evaluating tag placement accuracy: tagged BLEU scores and flagrant-failure counts.

The previous section indicated that training-data augmentation did not have a strong effect on translation quality of *content*. We now turn to tagged BLEU scores to see if they provide any signal as to the translation quality of *markup*. As shown in Table 3, we observe a small positive improvement for the masking approach: statistical difference in 17 of 30 cases, and +0.79 BLEU on average when compared to the detag-and-project baseline. This effect is strongest for French and for 15% augmentation. At 15% masked augmentation, four of six results achieve statistical significance, and the average improvement is 1.00 BLEU. The best results for raw XLIFF systems appear scattered: the highest BLEU gains at 10% augmentation, the most consistent at 2%, and statistical significance achieved at least once everywhere except at 5% augmentation and in EN–DE.

We cross-check these conclusions by examining the flagrant failure rates. This analysis shows an extreme variability by test set. No configuration reaches more than a 3.0% failure rate on the EUR-Lex test set or 5.2% on the glossary test set. However, the increased diversity of tag indexes and tag patterns in the EUR-Lex mono test set provides for a much higher rate: up to 24.7% in the worst case. The full count of flagrant failures on the mono test set is displayed in Table 4.

By hard-coded design, the detag-and-project approach is not capable of changing, dropping, mutilating, or adding tags — they are placed without modification as a post-process after translation. We find that this technique also does not commit any flagrant errors of tag nesting on our test sets. Similar hard-coded limits affect the masking approach; the one instance of a dropped tag that we recorded is due to a tokenization error. Masking does, however, commit a certain number of nesting mistakes.[8] The raw-tag approach is susceptible to all kinds of flagrant failures. We note that, surprisingly, the number of errors tends to *increase* as more tagged examples are added to the training data in German and French, while Hungarian (with much smaller training data) does not show a clear pattern in any direction.

Increased errors in German are primarily due to more tags being generated with incorrect `id` parameters. Recall that our settings for tag injection (Section 5.1) introduce no more than two tag pairs into any sentence pair, resulting in a maximum `id` value of 2. The only examples of indexes beyond 2 in the training data come from the addition of tag self-translations (Section 4), which we include for indexes up to 20. These higher indexes never occur in the context of any content, and their relative prominence in the training data decreases as more tag-injected data is added, so the MT system may become less and less sure how to "translate" them in practice. The failures for German confirm this pattern. At 1% augmentation, all 30 tags with their IDs incorrectly changed have values beyond 2, but the MT system produces a different value beyond 2 in five cases. At 15% augmentation, the system does not propose a value beyond 2 in any of the 206 failure cases.

Arguably, the increased training focus on low-

[8] This count would include tags natively dropped by the MT system but re-added to the end of the output by rule. Masked systems produce on average 3% more line-final tags than raw systems, but essentially the same number as the baseline.

Table 4: Flagrant failure counts on the EUR-Lex mono tagged test set. ("DP" = detag and project.) Tag translation failures increase rapidly as the training data is augmented with more raw tags.

index tags should be equally true of the mask-based systems. A key difference is illustrated by the rise in mutilated tags for French. Masked tags are always expressed as single tokens; if the self-translated examples are enough to induce a copy-through behavior for them, the behavior can be correctly applied in any content segment regardless of context. However, raw tags are expressed as at least two and sometimes more tokens (cf. Figure 2), which turn out to have wildly different frequencies in the training data as augmentation increases.

Figure 3 illustrates the BPE pieces involved in translating the raw tags `<g id="2">` and `<g id="3">` from English to French, along with the observed frequencies of those tokens in the training data. For a low-index tag, the tokens are quite common and, moreover, have relatively balanced counts: the opening token is seen roughly 2.4 times as often as the closing token no matter the data augmentation percentage. The situation is markedly different for a higher-index tag. In this case, increasing amounts of tag injection heavily shift vocabulary mass toward the opening token: it already appears 58 times more frequently than the tail at 1% augmentation, a ratio that grows to 1022 at 15%.

This extreme imbalance may be responsible for the 15% model's tag mutilation behavior. On our mono test set, this model never produces the first token of a tag without the tail, nor does it mutilate any tags for indexes up to 2. All the mutilation failures are caused by producing the tail alone for higher indexes, e.g. `id="3">` — exactly corresponding to the string of low-frequency tokens where a copy-through behavior can be easily learned.

6.4 Human Evaluation of Tag Placement

We conduct a human evaluation of tag placement accuracy in order to get a more complete picture of errors than afforded by tagged BLEU scores and flagrant-failure counts. Since it is impractical to

(a) Lines with indexes 1 and 2 only

Lang	System	Good	Bad	Residual
EN–DE	detag/project	97.3%	2.7%	0.0%
	masked (15%)	98.6%	1.4%	0.0%
	raw (1%)	98.4%	1.6%	0.0%
EN–FR	detag/project	92.9%	4.0%	3.1%
	masked (15%)	97.0%	0.5%	2.5%
	raw (1%)	96.1%	1.4%	2.5%
EN–HU	detag/project	93.8%	4.9%	1.3%
	masked (15%)	96.9%	2.5%	0.9%
	raw (10%)	96.1%	3.0%	0.9%

(b) Lines with indexes 3 and above

Lang	System	Good	Bad	Residual
EN–DE	detag/project	87.3%	12.7%	0.0%
	masked (15%)	84.2%	15.8%	0.0%
	raw (1%)	83.6%	16.0%	0.4%
EN–FR	detag/project	77.7%	9.8%	12.5%
	masked (15%)	78.7%	9.0%	12.3%
	raw (1%)	80.8%	6.2%	12.9%
EN–HU	detag/project	77.9%	19.3%	2.7%
	masked (15%)	70.9%	19.5%	9.6%
	raw (10%)	33.0%	63.8%	3.2%

Table 5: Summarized human evaluation of tag placement accuracy.

collect judgements on full test sets for all 33 experiments, we restrict this study to subsets of both. In terms of systems, we evaluate the detag-and-project baseline, the 15% masked augmentation, and either the 1% raw (EN–DE, EN–FR) or 10% raw (EN–HU) augmentation. For data, we use the entire glossary test set (289 lines), all the lines in the EUR-Lex monolingual test set containing tag indexes 3 and above (283 lines), and an equal number of randomly sampled lines from the same test set containing indexes 1 and 2 only.

In summarizing the results, we collapse the eight annotation types into three categories. "Good" tags are those placed correctly in the output, including if they were correctly deleted or duplicated. "Bad" tags are incorrectly placed, incorrectly dropped or duplicated, hallucinated, or mutilated in the output. "Residual" tags are those judged as impossible or unclear to place. Given the marked difference in flagrant failures observed for tag indexes 1 and 2 versus 3 and beyond, we report human judgements separately by whether the input included indexes beyond 2 or not. These summarized results appear in Table 5.

Placement for low-index tags present in the augmented training data is learned quite well: in all language pairs, the masked and raw-tag systems outperform the detag-and-project baseline. Humans also find the annotation of inputs with few tags to be a straightforward task, as very few tags are marked as awkward to place.

Results are less clear-cut on high-index tags that appear in training only as self-translated examples. Word-alignment-based projection works best in EN–DE and EN–HU. Translating raw tags does well in EN–DE and EN–FR but is unusable in EN–HU. The masking approach performs consistently in second place. Especially in French, the human task of judging placement accuracy has become notably harder, an effect that could also significantly affect the good/bad results of any method.

7 Conclusion

We have performed a comprehensive evaluation of several tag representation methods and proposed a data-augmentation technique that allows MT models to jointly learn content translation and inline tag placement.

Results show that representing tags as masks, together with data augmentation, leads to equivalent or improved performance over a detag-and-project approach: placement accuracy is higher for tags frequent in the training data, while it may vary for tags never observed in context. In practice, it may be preferable to rely on the MT model's ability to learn mask placement — even with some variability in accuracy — than to implement, debug, and maintain the baseline's more complicated projection rules and the required alignment model.

Raw tags, on the other hand, fail our generalization tests. Though placement accuracy is again baseline-beating for commonly observed tags, raw models seem unable to copy rare tags into the output without a significant number of mutilations, deletions, and duplications: an unacceptable result for the goal of obtaining well-structured output.

Several changes to our setup may improve the transfer of raw tags. Injecting XLIFF tags with a wider variety of `id` values is needed to expose the model to them in context instead of merely in self-translation. Explicitly identifying tag tokens via input factors (Dinu et al., 2019), or constraining/promoting the output of complete tags (Hashimoto et al., 2019), would also be helpful for reducing the rate of malformed output.

Acknowledgements

We thank Yaser Al-Onaizan, Marcello Federico, Stanislas Lauly, and Prashant Mathur for early discussions regarding the tag-injection technique.

A Train, Dev, and Test Corpora

Table 6 gives a more detailed account of our training resources, showing the amount of material sourced from each standard WMT corpora we use. Following Figure 2 of Schwenk et al. (2019), we reduce the EN–DE WikiMatrix corpus to only those lines with a margin threshold of 1.05 or higher *and* where the WMT-provided language detection registered English on the source and German on the target. This is in addition to ignoring Common Crawl and Paracrawl entirely. For EN–FR, we discard the Common Crawl and Giga-FrEn corpora.

Clean-up on the training data is limited to removing lines where the source and/or target side is blank, removing lines whose source side is contained in one of our dev or test sets, tokenization, byte-pair encoding (Sennrich et al., 2016) using 32,000 operations, and length-based filtering. In this final step, we remove sentence pairs of more than 95 tokens on either side, containing tokens with more than 100 characters, or where the length ratio between source and target is too unbalanced.

B Additional Results

Table 8 (on the next page) shows complete results on translating *untagged* test sets, to ensure that adding masked or raw tags to our training data does not adversely affect the translation of plain content. BLEU scores are computed according to SacreBLEU (Post, 2018), while statistical significance uses 1000 trials of stratified approximate randomization (Yeh, 2000). The small glossary test set shows the highest BLEU variance, but only once to statistical significance. Meanwhile, the few significant differences are scattered across language pairs, test sets, tag representations, and augmentation percentages.

The Tatoeba Translation Challenge – Realistic Data Sets for Low Resource and Multilingual MT

Jörg Tiedemann
University of Helsinki
jorg.tiedemann@helsinki.fi
https://github.com/Helsinki-NLP/Tatoeba-Challenge

Abstract

This paper describes the development of a new benchmark for machine translation that provides training and test data for thousands of language pairs covering over 500 languages and tools for creating state-of-the-art translation models from that collection. The main goal is to trigger the development of open translation tools and models with a much broader coverage of the World's languages. Using the package it is possible to work on realistic low-resource scenarios avoiding artificially reduced setups that are common when demonstrating zero-shot or few-shot learning. For the first time, this package provides a comprehensive collection of diverse data sets in hundreds of languages with systematic language and script annotation and data splits to extend the narrow coverage of existing benchmarks. Together with the data release, we also provide a growing number of pre-trained baseline models for individual language pairs and selected language groups.

1 Introduction

The Tatoeba translation challenge includes shuffled training data taken from OPUS,[1] an open collection of parallel corpora (Tiedemann, 2012), and test data from Tatoeba,[2] a crowd-sourced collection of user-provided translations in a large number of languages. All data sets are labeled with ISO-639-3 language codes using macro-languages in case when available. Naturally, training data do not include sentences from Tatoeba and neither from the popular WMT testsets to allow a fair comparison to other models that have been evaluated using those data sets.

Here, we propose an open challenge and the idea is to encourage people to develop machine translation in real-world cases for many languages. The most important point is to get away from artificial setups that only simulate low-resource scenarios or zero-shot translations. A lot of research is tested with multi-parallel data sets and high resource languages using data sets such as WIT^3 (Cettolo et al., 2012) or Europarl (Koehn, 2005) simply reducing or taking away one language pair for arguing about the capabilities of learning translation with little or without explicit training data for the language pair in question (see, e.g., Firat et al. (2016a,b); Ha et al. (2016); Lakew et al. (2018)). Such a setup is, however, not realistic and most probably over-estimates the ability of transfer learning making claims that do not necessarily carry over towards real-world tasks.

In the set we provide here we, instead, include all available data from the collection without removing anything. In this way, the data refers to a diverse and skewed collection, which reflects the real situation we need to work with and many low-resource languages are only represented by noisy or very unrelated training data. Zero-shot scenarios are only tested if no data is available in any of the sub-corpora. More details about the data compilation and releases will be given below.

Tatoeba is, admittedly, a rather easy test set in general but it includes a wide variety of languages and makes it easy to get started with rather encouraging results even for lesser resourced languages. The release also includes medium and high resource settings and allows a wide range of experiments with all supported language pairs including studies of transfer learning and pivot-based methods.

2 Data releases

The current release includes over 500GB of compressed data for 2,961 language pairs covering 555 languages. The data sets are released per language

data/deu-eng/train.id.gz
data/deu-eng/dev.id
data/deu-eng/dev.src
data/deu-eng/dev.trg
data/deu-eng/test.src
data/deu-eng/test.trg
data/deu-eng/test.id
```

Figure 1: Released data packages: training data, development data and test data. Language labels are stored in ID files that also contain the name of the source corpus for the training data sets.

Files with the extension *.src* refer to sentences in the source language (*deu* in this case) and files with extension *.trg* contain sentences in the target language (*eng* here). File with extension *.id* include the ISO-639-3 language labels with possibly extensions about the orthographic script (more information below). In the *.id* file for the training data there are also labels for the OPUS corpus the sentences come from. We include the entire collection available from OPUS with data from the following corpora: ada83, Bianet, bible-uedin, Books, CAPES, DGT, DOGC, ECB, EhuHac, EiTB-ParCC, Elhuyar, EMEA, EUbookshop, EUconst, Europarl, Finlex, fiskmo, giga-fren, GlobalVoices, GNOME, hrenWaC, infopankki, JRC-Acquis, JW300, KDE4, KDEdoc, komi, MBS, memat, MontenegrinSubs, MultiParaCrawl, MultiUN, News-Commentary, OfisPublik, OpenOffice, OpenSubtitles, ParaCrawl, PHP, QED, RF, sardware, SciELO, SETIMES, SPC, Tanzil, TED2013, TedTalks, TEP, TildeMODEL, Ubuntu, UN, UNPC, wikimedia, Wikipedia, WikiSource, XhosaNavy.

The data sets are compiled from the pre-aligned bitexts but further cleaned in various ways. First of all, we remove non-printable characters and strings that violate Unicode encoding principles using regular expressions and a recoding trick using the forced encoding mode of *recode* (v3.7), a popular character conversion tool.[3] Furthermore, we also de-escape special characters (like '&' encoded as '&') that may appear in some of the corpora. For that, we apply the tools from Moses (Koehn et al., 2007). Finally, we also apply automatic language identification to remove additional noise from the data. We use the compact language detect library (CLD2) through its Python bindings[4] and a Python library for converting between different ISO-639 standards.[5] CLD2 supports 172 languages and we use the options for "best effort" and apply the assumed language from the original data as the "hint language code". For unsupported languages, we remove all examples that are detected to be English as this is a common problem in some corpora where English texts appear in various places (e.g. untranslated text in localization data of community efforts). In all cases, we only rely on the detected language if it is flagged as reliable by the software.

All corpus data and sub-languages are merged and shuffled using terashuf[6] that is capable to efficiently shuffle large data sets. But we keep track of the original data set and provide labels to recognize the origin. In this way, it is possible to restrict training to specific subsets of the data to improve domain match or to reduce noise. The entire procedure of compiling the Tatoeba Challenge data sets is available from the project repository at https://github.com/Helsinki-NLP/Tatoeba-Challenge.

The largest data set (English-French) contains over 180 million aligned sentence pairs and 173 language pairs are covered by over 10 million sentence pairs in our collection. Altogether, there are almost bilingual 3,000 data sets and we plan regular updates to improve the coverage. Below, we give some more details about the language labels, test sets and monolingual data sets that we include in the package as well.

2.1 Language labels and scripts

We label all data sets with standardized language codes using three-letter codes from ISO-639-3. The labels are converted from the original OPUS language IDs (which roughly follow ISO-639-1 codes but also include various non-standard IDs) and information about the writing system (or script) is automatically assigned using Unicode regular expressions and counting letters from specific script character properties. For the scripts we use four-letter codes from ISO-15924 and attach them to the three-letter language codes defined in ISO-639-3. Only the most frequently present script in a string is shown. Mixed content may appear but is not marked specifically. Note that the code Zyyy

[3] https://github.com/pinard/Recode

[4] https://pypi.org/project/pycld2/

[5] https://pypi.org/project/iso-639/

[6] https://github.com/alexandres/terashuf

refers to common characters that cannot be used to distinguish scripts. The information about the script is not added if there is only one script in that language and no other scripts are detected in any of the strings. If there is a default script among several alternatives then this particular script is not shown either. Note that the assignment is done fully automatically and no corrections have been made. Three example label sets are given below using the macro-languages Chinese (zho), Serbo-Croatian (hbs) and Japanese (jpn) that can use character from different scripts:

Chinese: cjy_Hans, cjy_Hant, cmn, cmn_Bopo, cmn_Hans, cmn_Hant, cmn_Latn, gan, lzh, lzh_Bopo, lzh_Hang, lzh_Hani, lzh_Hans, lzh_Hira, lzh_Kana, lzh_Yiii, nan_Hani, nan_Latn, wuu, wuu_Bopo, wuu_Hang, wuu_Hani, wuu_Hira, yue_Hans, yue_Hant, yue_Latn

Japanese: jpn, jpn_Hani, jpn_Hira, jpn_Kana, jpn_Latn

Serbo-Croatian: bos_Latn, hrv, srp_Cyrl, srp_Latn

This demonstrates that a data set may include examples from various sub-languages if they exist (e.g. Bosnian, Croatian and Serbian in the Serbo-Croatian case) or language IDs with script extensions that show the dominating script in the corresponding string (e.g. Cyrl for Cyrillic or Latn for Latin script). Those labels can be used to separate the data sets, to test sub-languages or specific scripts only or to remove some noise (like the examples that are tagged with the Latin script (Latn) in the Japanese data set. Note that script detection can also fail in which the corresponding code is missing or potentially wrong. For example, the detection of traditional (Hant) och simplified Chinese (Hans) can be ambiguous and encoding noise can have an effect on the detection.

We also release the tools that we developed for converting and standardizing OPUS IDs and also the tools that detect scripts and variants of writing systems. The package is available from github[7] and can be installed from CPAN.[8]

2.2 Multiple reference translations

Test and development data are taken from a shuffled version of Tatoeba. All translation alternatives are included in the data set to obtain the best coverage of languages in the collection. Development and test sets are disjoint in the sense that they do not include identical source-target language sentence pairs. However, there can be identical source sentences or identical target sentences in both sets, which are not linked to the same translations. Similarly, there can be identical source or target sentences in one of the sets, for example the test set, with different translations. In Figure 2, you can see examples from the Esperanto-Ladino test set.

epo	lad_Latn
u vi estas en Berlino?	Estash en Berlin?
u vi estas en Berlino?	Vos estash en Berlin?
u vi estas en Berlino?	Vozotras estash en Berlin?
La hundo estas nigra.	El perro es preto.
La hundo nigras.	El perro es preto.

Figure 2: Examples of test sentences with multiple reference translations taken from the Esperanto-Ladino test set.

The test data could have been organized as multi-reference data sets but this would require to provide different sets in both translation directions. Removing alternative translations is also not a good option as this would take away a lot of relevant data. Hence, we decided to provide the data sets as they are, which implicitly creates multi-reference test sets but with the wrong normalization.

2.3 Monolingual data

In addition to the parallel data sets we also provide monolingual data that can be used for unsupervised methods or data augmentation approaches such as back-translation. For that purpose, we extract public data from Wikimedia including source from Wikpedia, Wikibooks, Wikinews, Wikiquote and Wikisource. We extract sentences from data dumps provided in JSON format[9] and process them with jq,[10] a lightweight JSON processing tool. We apply the same cleaning steps as we do for the OPUS bitexts including language identification and convert language IDs to ISO-639-3 as before. Sentence boundaries are detected using UDPipe (Straka et al., 2016) with models trained on universal dependency treebanks v 2.4 and the Moses sentence splitter with language-specific non-breaking prefixes if available. We preserve document boundaries and do not shuffle the data to enable experiments with discourse-aware models. The data sets are released along with the rest of the Tatoeba challenge data.

3 The translation challenge

The main challenge is to develop translation models and to test them with the given test data from

[7] https://github.com/Helsinki-NLP/LanguageCodes

[8] https://metacpan.org/pod/ISO::639::3 and https://metacpan.org/pod/ISO::639::5

[9] https://dumps.wikimedia.org/other/cirrussearch/current

[10] https://stedolan.github.io/jq/

Tatoeba. The focus is on low-resource languages and to push their coverage and translation quality. Resources for high-resource are also provided and can be used as well for translation modeling of those languages and for knowledge transfer to less resourced languages. Note that not all language pairs have sufficient data sets for test, development (dev) and training ($train$) data. Hence, we divided the Tatoeba challenge data into various subsets based on the size of the training data available.

high-resource settings: 298 language pairs with training data of at least one million training examples (aligned sentence pairs), we further split into language pairs with more than 10 million training examples (173 language pairs) and other language pairs with data sets below the size of 10 million examples

medium-sized resource settings: 97 language pairs with more than 100,000 and less than 1 million training examples

low-resource settings: 87 language pairs with less than 100,000 training examples, we further distinguish between language pairs with more than 10,000 training examples (63) and language pairs below 10,000 training examples (24)

zero-shot translation: language pairs with no training data (40 in the current data set)

For all those 522 selected language pairs, the data set provides at least 200 sentences per test set. 101 of them involves English as one of the languages. 288 test sets contain more than 1,000 sentence pairs of which only 68 include English. Note, that everything below 1,000 sentences is probably not very reliable as a proper test set but we decided to release smaller test sets as an initial benchmark to trigger further development even for extremely under-resourced language pairs. We also decided to use very low thresholds for the division into low-resource languages. Having 10,000 training examples or less is very realistic for many real-world examples and we want to encourage the work on such cases in particular.

The maximum size of test sets in our collection is 10,000 sentence pairs, which is available for 76 language pairs. The test size is reduced to 5,000 if there is less than 20,000 sentence pairs in Tatoeba (19 data sets). The remaining sentences are released as disjoint validation data. For 48 Tatoeba language pairs with less than 10,000 sentence pairs, we keep 2,500 for the test set and the rest for validation and for 78 Tateoba language pairs with less than 5,000 sentence pairs we keep 1,000 for validation and the rest for testing. Finally, for language pairs with less than 2,000 sentences in Tatoeba we skip validation data and use everything for test purposes.

Test and validation data are strictly disjoint and none of the examples from Tatoeba are explicitly included in the training data. However, as it is common in realistic cases, there is a natural chance for a certain overlap between those data sets. Figure 3 plots the percentage of sentence pairs in test and validation sets that can also be found in the corresponding training data we release. The average proportion is rather low around 5.5% for both with a median percentage of 2.3% and 2.9% for test and validation data, respectively. There is one clear outlier with a very high proportion of over 55% overlap and that is Danish–English for some reason that is not entirely clear to us. Otherwise, the values are well below that ratio.

4 The data challenge

The most important ingredient for improved translation quality is data. It is not only about training data but very much also about appropriate test data that can help to push the development of transfer models and other ideas of handling low-resource settings. Therefore, another challenge we want to open here is the increase of the coverage of test sets for low-resource languages. Our strategy is to organize the extension of the benchmarks directly through the Tatoeba initiative. Users who would like to contribute to further MT benchmark development are asked to register for the open service provided by Tatoeba and to upload new translations in the languages of interest. From our side, we will continuously update our challenge data set to include the latest data releases coming from Tatoeba including new language pairs and extended data sets for existing language pairs. We will make sure that the new test sets do not overlap with any released development data from previous revisions to enable fair comparisons of old models with new benchmarks. The extended test and validation data sets will be released as new packages and old revisions will be kept for replicability of existing

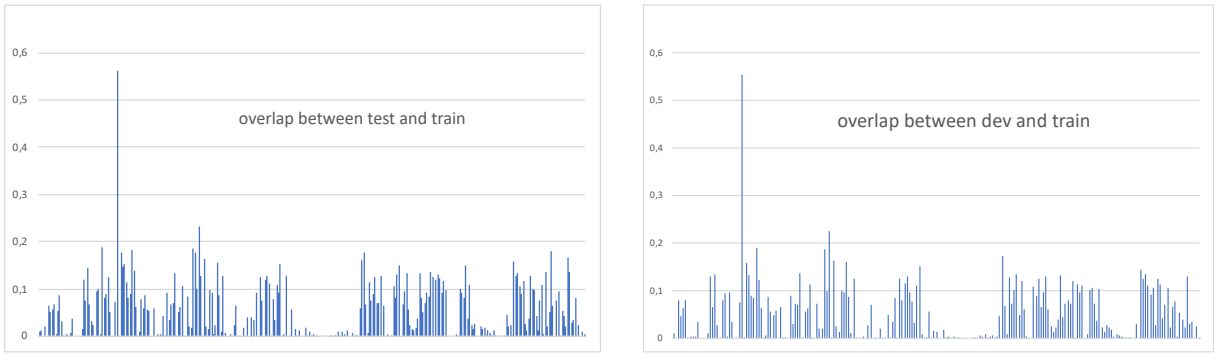

Figure 3: Overlap between test and validation (dev) data and the training data: Proportion of sentence pairs that exist in the training data for all data sets above 1,000 sentence pairs.

scores.

In order to provide information about language pairs in need, we provide a list of data sets with less than 1,000 examples per language pair. In the current release, this refers to 2,375 language pairs. 2,141 language pairs have less than 200 translation units and are, therefore, not included in the released benchmark test set. Furthermore, we also provide a list of languages for which we release training data coupled with English but no test data is available from Tatoeba. Currently, this relates to 246 languages.

We encourage users to especially contribute translations for those data sets in order to improve the language coverage even further. We hope to trigger a grass-root development that can significantly boost the availability of development and test sets as one of the crucial elements for pushing NMT development in the corresponding languages.

Finally, we also encourage to incorporate other test sets besides of the Tatoeba data. Currently, we also test with WMT news test sets for the language pairs that are covered by the released development and test sets over the years of the news translation campaign. Contributions and links can be provided through the repository management interface at github.

5 How to participate

The goal of the data release is to enable a straightforward setup for machine translation development. Everyone interested is free to use the data for their own development. A leader board for individual language pairs will be maintained. Furthermore, we also intend to make models available that are listed in the challenge. This does not only support replicability but also provides a new unique resource of pre-trained models that can be integrated in real-world applications or can be used in further research, unrelated downstream tasks or as a starting point for subsequent fine-tuning and domain adaptation. A large number of models is already available from our side providing baselines for a large portion of the data set. More details will be provided below.

For participation, there are certain rules that apply:

- Do not use any development or test data for training (dev can be used for validation during training as an early stopping criterion).
- Only use the provided training data for training models with comparable results in constrained settings. Any combination of language pairs is fine or backtranslation of sentences included in training data for any language pair is allowed, too. That means that additional data sets, parallel or monolingual, are not allowed for official models to be compared with others.
- Unconstrained models may also be trained and can be reported as a separate category. Using pre-trained language or translation models fall into the unconstrained category. Make sure that the pre-trained model does not include Tatoeba data that we reserve for testing.
- We encourage to release models openly to ensure replicability and re-use of pre-trained models. If you want to enter the official leader board you have to make your model available including instructions on how to use them.

6 Baseline Models

Along with the data, we also release baseline models that we train with state-of-the-art trans-

former models (Vaswani et al., 2017) using Marian-NMT,[11] a stable production-ready NMT toolbox with efficient training and decoding capabilities (Junczys-Dowmunt et al., 2018). We apply a common setup with 6 self-attentive layers in both, the encoder and decoder network using 8 attention heads in each layer. The hyper-parameters follow the general recommendations given in the documentation of the software.[12] The training procedures follow the strategy implemented in OPUS-MT (Tiedemann and Thottingal, 2020) and detailed instructions are available from github.[13]

We train a selection of models on v100 GPUs with early-stopping after 10 iterations of dropping validation perplexities. We use SentencePiece (Kudo and Richardson, 2018) for the segmentation into subword units and apply a shared vocabulary of a maximum of 65,000 items. Language label tokens in the spirit of Johnson et al. (2017) are used in case of multiple language variants or scripts in the target language. Models for over 400 language pairs are currently available and we refer the reader to the website with the latest results. For illustration, we provide some example scores below in Table 1 using automatic evaluation based on chrF2 and BLEU computed using sacrebleu (Post, 2018). The actual translations are also available for each model and the distribution comes along with the logfiles from the training process and all necessary data files such as the SentencePiece models and vocabularies.

language pair	chrF2	BLEU
aze-eng	0.490	31.9
bel-eng	0.268	10.0
cat-eng	0.668	50.2
eng-epo	0.577	35.6
eng-glg	0.593	37.8
eng-hye	0.404	16.6
eng-ilo	0.569	30.8
eng-run	0.436	10.4

Table 1: Translations scores from baseline models trained for a selection of medium-size language pairs (according to our classification) tested on the provided Tatoeba benchmark. We show here models that include English and score above 10 BLEU.

7 Multilingual Models

One of the most interesting questions is the ability of multilingual models to push the performance of low-resource machine translation. The Tatoeba translation challenge provides a perfect testbed for systematic studies on the effect of transfer learning across various subsets of language pairs. We already started various experiments with a number of multilingual translation models that we evaluate on the given benchmarks. In our current work, we focus on models that include languages in established groups and for that we facilitate the ISO-639-5 standard. This standard defines a hierarchy of language groups and we map our data sets accordingly to start new models that cover those sets. As an example, we look at the task of Belorussian-English translation that has been included in the previous section as well. Table 2 summarizes the results of our current models sorted by chrF2 scores.

model	chr-F2	BLEU
sla-eng/opus4m	0.610	42.7
sla-eng/opus2m	0.609	42.5
sla-eng/opus1m	0.599	41.7
ine-eng/opus2m	0.597	42.2
ine-eng/opus4m	0.597	41.7
ine-eng/opus1m	0.588	41.0
zle-eng/opus4m	0.573	38.7
zle-eng/opus2m	0.569	38.3
mul-eng/opus1m	0.550	37.0
mul-eng/opus2m	0.549	36.8
zle-eng/opus1m	0.543	35.4
ine-ine/opus1m	0.512	31.8
bel-eng/opus	0.268	10.0

Table 2: Translation results of the Belorussian-English test set using various multilingual translation models compared to the baseline bilingual model (shown at the bottom). opusXm refers to sampled data sets that include X million sentences per language pair.

The models focus on different levels of relatedness of the languages and range from East Slavic Languages (zle), Slavic languages (sla) to the language family of Indo-European languages (ine) and the set that contains all languages (mul). Each model is trained on sampled data set in order to balance between different languages. The smallest training sets are based on data that are sampled to include a maximum of one million sentence per language pair (opus1m). We use both, down-sampling and up-sampling. The latter is done by simply

multiplying the existing data until the threshold is reached. We also set a threshold of 50 for the maximum of repeating the same data in order to avoid over-representing small noisy data. The one-million models are trained first and form the basis of larger models. We continue training with data sets sampled to two million before increasing to four million sentence pairs.

The Table shows some interesting patterns. First of all, we can clearly see a big push in performance when adding related languages to the training data. This is certainly expected especially in the case of Belorussian that is closely related to higher-resource-languages such as Russian and Ukrainian. Interesting is that the East Slavic language group is not the best performing model even though it includes those two related languages. The additional information from other Slavic languages pushes the performance beyond their level quite significantly. Certainly, those models will see more data and this may cause the difference. The 'sla-eng' model covers 13 source languages whereas 'zle' only 5. Also interesting to see is that the Indo-European language model fairs quite well despite the enormous language coverage that this model has to cope with. On the other hand, the big 'mul' translation model does not manage to create the same performance and the limits of the standard model with such a massive setup become apparent. Training those models becomes also extremely expensive and slow and we did not manage to start the 4-million-sentence model.

Currently, we look into the various models we train and many other interesting patterns can be seen. We will leave a careful analyses to future work and also encourage the community to explore this field further using the given collection and benchmark. Updates about models and scores will be published on the website and we would also encourage more qualitative studies that we were not able to do yet.

8 Zero-shot and few-shot translation

Finally, we have a quick look at zero-shot and few-shot translation tasks. Table 3 shows results for Awadhi-English translation, one of the test sets for which no training data is available. Awadhi is an Eastern Hindi language in the Indo-Iranian branch of the Indo-European language family.[14]

[14]We use ISO639-3 and ISO639-5 standards for names and codes of languages and language groups.

model	chr-F2	BLEU
ine-eng/opus1m	0.285	10.0
mul-eng/opus1m	0.257	9.4
inc-eng/opus1m	0.217	6.8
iir-eng/opus1m	0.214	7.9
ine-ine/opus1m	0.201	2.4
tatoeba-zero/opus	0.042	0.1

Table 3: Translation results of the Awadhi-English test set using multilingual translation models.

The table shows that a naive approach of throwing all languages that are part of zero-shot language pairs into one global multilingual model (tatoeba-zero) does not work well. This is probably not very surprising. Another interesting observation is that a symmetric multilingual model with Indo-European languages on both sides (ine-ine) also underperforms compared to other multilingual models that only translate into English. Once again, the Indo-European-language-family to English model performs quite well. Note that the performance purely comes from overlaps with related languages as no Awadhi language data is available during training. The performance is still very poor and needs to be taken with a grain of salt. They demonstrate, however, the challenges one faces with realistic cases of zero-shot translation.

In Table 4, we illustrate another case that could be described as a realistic few-shot translation task. Our collection comes with 3,613 training examples for the translation between English and Faroese. The table shows our current results in this task using multilingual models that translate from English to language groups including the Scandinavian language in question.

model	chr-F2	BLEU
eng-gem/opus	0.318	9.4
gem-gem/opus	0.312	7.0
eng-gmq/opus	0.311	7.0
eng-ine/opus	0.281	6.3
eng-mul/opus	0.280	5.7
ine-ine/opus	0.276	5.9
tatoeba-zero/opus	0.042	0.1

Table 4: Translation results of the English-Faroese test set with different multilingual NMT models.

Again, we can see that the naive tatoeba-zero model is the worst. The symmetric Indo-European model performs better but the English-Germanic

model gives the best performance, which is still very low and not satisfactory for real-world applications. Once again, the example demonstrates the challenge that is posed by extremely low-resource scenarios and we hope that the data set we provide will trigger additional fascinating studies on a large variety of interesting cases.

9 Comparison to the WMT news task

Finally, we also include a quick comparison to the WMT news translation task, see Table 5. Note that we did not perform any optimization for that task, did not use any in-domain back-translations and did not run fine-tuning in the news domain. We only give results for English–German (in both directions) for the 2019 test data to give an impression about the released baseline models.

English – German		
model	BLEU	chr-F2
eng-deu	42.4	0.664
eng-gmw	35.9	0.616
eng-gem	35.0	0.613
eng-ine	26.6	0.554
eng-mul	21.0	0.512
WMT best	44.9	–
German – English		
model	BLEU	chr-F2
deu-eng	40.5	0.645
gmw-eng	36.6	0.615
gem-eng	37.2	0.618
ine-eng	31.7	0.571
mul-eng	27.0	0.529
WMT best	42.8	–

Table 5: Translation results of baseline models on English–German news translation from WMT 2019 using bilingual and multilingual Tatoeba baseline models. The BLEU scores are also compared to the best score that is currently available from http://matrix.statmt.org/matrix – retrieved on October 4, 2020.

The results demonstrate that the models can achieve high quality even on a domain they are not optimized for. The best scores in the German–English case are close to the top performing model registered for this task even though the comparison is not fair for various reasons. The purpose is anyway not to provide state-of-the-art models for the news translation task but baseline models for the Tatoeba case and in future work we will also explore the use of our models as the basis for systems that can be developed for other benchmarks and applications. In the example we can also see that multilingual models significantly lag behind bilingual ones in high-resource cases. Each increase of the language coverage (except for the move from West Germanic languages (gmw) to Germanic languages (gem) in the German–English case) leads to a drop in performance but note that those multilingual models are not fine-tuned for translating from and to German.

10 Conclusions

This paper presents a new comprehensive data set and benchmark for machine translation that covers roughly 3,000 language pairs and over 500 languages and language variants. We provide training and test data that can be used to explore realistic low-resource scenarios and zero-shot machine translation. The data set is carefully annotated with standardized language labels including variations in scripts and with information about the original source. We also release baseline models and results and encourage the community to contribute to the data set and machine translation development. All tools for data preparation and training bilingual as well as multilingual translation models are provided as open source packages on github. We are looking forward to new models, extended test sets and a better coverage of the World's languages.

Human-Paraphrased References Improve Neural Machine Translation

Markus Freitag, George Foster, David Grangier, Colin Cherry
Google Research
{freitag,fosterg,grangier,colincherry}@google.com

Abstract

Automatic evaluation comparing candidate translations to human-generated paraphrases of reference translations has recently been proposed by Freitag et al. (2020). When used in place of original references, the paraphrased versions produce metric scores that correlate better with human judgment. This effect holds for a variety of different automatic metrics, and tends to favor natural formulations over more literal (*translationese*) ones. In this paper we compare the results of performing end-to-end system development using standard and paraphrased references. With state-of-the-art English-German NMT components, we show that tuning to paraphrased references produces a system that is significantly better according to human judgment, but 5 BLEU points worse when tested on standard references. Our work confirms the finding that paraphrased references yield metric scores that correlate better with human judgment, and demonstrates for the first time that using these scores for system development can lead to significant improvements.

1 Introduction

Machine Translation (MT) has shown impressive progress in recent years. Neural architectures (Bahdanau et al., 2015; Gehring et al., 2017; Vaswani et al., 2017) have greatly contributed to this improvement, especially for languages with abundant training data (Bojar et al., 2016, 2018; Barrault et al., 2019). This progress creates novel challenges for the evaluation of machine translation, both for human (Toral, 2020; Läubli et al., 2020) and automated evaluation protocols (Lo, 2019; Zhang et al., 2019).

Both types of evaluation play an important role in machine translation (Koehn, 2010). While human evaluations provide a gold standard evaluation, they involve a fair amount of careful and hence expensive work by human assessors. Cost therefore limits the scale of their application. On the other hand, automated evaluations are much less expensive. They typically only involve human labor when collecting human reference translations and can hence be run at scale to compare a wide range of systems or validate design decisions. The value of automatic evaluations therefore resides in their capacity to be used as a proxy for human evaluations for large scale comparisons and system development.

The recent progress in MT has raised concerns about whether automated evaluation methodologies reliably reflect human ratings in high accuracy ranges. In particular, it has been observed that the best systems according to humans might fare less well with automated metrics (Barrault et al., 2019). Most metrics such as BLEU (Papineni et al., 2002) and TER (Snover et al., 2006) measure overlap between a system output and a human reference translation. More refined ways to compute such overlap have consequently been proposed (Banerjee and Lavie, 2005; Lo, 2019; Zhang et al., 2019).

Orthogonal to the work of building improved metrics, Freitag et al. (2020) hypothesized that human references are also an important factor in the reliability of automated evaluations. In particular, they observed that standard references exhibit simple, monotonic language due to human 'translationese' effects. These standard references might favor systems which excel at reproducing these effects, independent of the underlying translation quality. They showed that better correlation between human and automated evaluations could be obtained when replacing standard references with *paraphrased* references, even when still using surface overlap metrics such as BLEU (Papineni et al., 2002). The novel references, collected by asking linguists to paraphrase standard references, were shown to steer evaluation away from rewarding

Proceedings of the 5th Conference on Machine Translation (WMT), pages 1183–1192
Online, November 19–20, 2020.

translation artifacts. This improves the assessment of alternative, but equally good translations.

Our work builds on the success of paraphrased translations for evaluating existing systems, and asks if different design choices could have been made when designing a system with such an evaluation protocol in mind. This examination has several potential benefits: it can help identify choices which improve BLEU on standard references but have limited impact on final human evaluations; or those that result in better translations for the human reader, but worse in terms of standard reference BLEU. Conversely, it might turn out that paraphrased references are not robust enough to support system development due to the presence of 'metric honeypots': settings that produce poor translations, but which are nevertheless assigned high BLEU scores.

To address these points, we revisit the major design choices of the best English→German system from WMT2019 (Ng et al., 2019) step-by-step, and measure their impact on standard reference BLEU as well as on paraphrased BLEU. This allows us to measure the extent to which steps such as data cleaning, back-translation, fine-tuning, ensemble decoding and reranking benefit standard reference BLEU more than paraphrase BLEU. Revisiting these development choices with the two metrics results in two systems with quite different behaviors. We conduct a human evaluation for adequacy and fluency to assess the overall impact of designing a system using paraphrased BLEU.

Our main findings show that optimizing for paraphrased BLEU is advantageous for human evaluation when compared to an identical system optimized for standard BLEU. The system optimized for paraphrased BLEU significantly improves WMT newstest19 adequacy ratings (4.72 vs 4.27 on a six-point scale) and fluency ratings (63.8% vs 27.2% on side-by-side preference) despite scoring 5 BLEU points lower on standard references.

2 Related Work

Collecting human paraphrases of existing references has recently been shown to be useful for system evaluation (Freitag et al., 2020). Our work considers applying the same methodology for system tuning. There is some earlier work relying on *automated* paraphrases for system tuning, especially for Statistical Machine Translation (SMT). Madnani et al. (2007) introduced an automatic paraphrasing technique based on English-to-English translation of full sentences using a statistical MT system, and showed that this permitted reliable system tuning using half as much data. Similar automatic paraphrasing has also been used to augment training data, e.g. (Marton et al., 2009), but relying on standard references for evaluation. In contrast to human paraphrases, the quality of current machine generated paraphrases degrades significantly as overlap with the input decreases (Mallinson et al., 2017; Roy and Grangier, 2019). This makes their use difficult for evaluation since (Freitag et al., 2020) suggests that substantial paraphrasing – 'paraphrase as much as possible' – is necessary for evaluation.

Our work can be seen as replacing the regular BLEU metric with a new paraphrase BLEU metric for system tuning. Different alternative automatic evaluation metric have also been considered for system tuning (He and Way, 2010; Servan and Schwenk, 2011) with Minimum Error Rate Training, MERT (Och, 2003). This work showed some specific cases where Translation Error Rate (TER) was superior to BLEU.

Our work is also related to the bias that the human translation process introduces in the references, including source language artifacts—*Translationese* (Koppel and Ordan, 2011)—as well as source-independent artifacts—*Translation Universals* (Mauranen and Kujamäki, 2004). The professional translation community studies both systematic biases inherent to translated texts (Baker, 1993; Selinker, 1972), as well as biases resulting specifically from interference from the source text (Toury, 1995). For MT, Freitag et al. (2019) point at Translationese as a source of mismatch between BLEU and human evaluation, raising concerns that overlap-based metrics might reward hypotheses with translationese language more than hypotheses using more natural language. The impact of Translationese on human evaluation of MT has recently received attention as well (Toral et al., 2018; Zhang and Toral, 2019; Graham et al., 2019). More generally, the question of bias to a specific reference has also been raised, in the case of monolingual manual evaluation (Fomicheva and Specia, 2016; Ma et al., 2017). Different from the impact of Translationese on evaluation, the impact of Translationese in the training data has also been studied (Kurokawa et al., 2009; Lembersky et al., 2012a; Bogoychev and Sennrich, 2019; Riley et al., 2020).

Finally, our work is also related to studies measuring the importance of the test data quality, looking specifically at the test set translation direction. For SMT evaluation, Lembersky et al. (2012b) and Stymne (2017) explored how the translation direction affects translation results. Holmqvist et al. (2009) noted that the original language of the test sentences influences the BLEU score of translations. They showed that the BLEU scores for target-original sentences are on average higher than sentences that have their original source in a different language. Recently, a similar study was conducted for neural MT (Bogoychev and Sennrich, 2019).

3 Experimental Setup

We first describe data and models, then present our human evaluation protocol.

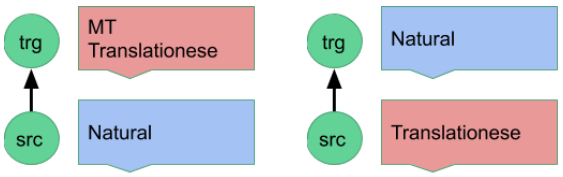
3.1 Data

We ran all experiments on the WMT 2019 English→German news translation task (Barrault et al., 2019). The task provides ∼38M parallel sentences. As German monolingual data, we concatenate all News Crawl data from 2007 to 2018, comprising ∼264M sentences after removing duplicates.

In addition to the training data, we use newstest2018 for development and newstest2019 for evaluation only. There is an important difference between these two test sets. Newstest2018 was created from monolingual news data from both English and German online sources. Half of the data consists of English text translated into German, while the other half consists of German text translated into English. This results in a joint test set of 2,998 sentences. Newstest2019, on the other hand, consists only of 1,997 sentences translated from English into German (see Figure 1). To provide a joint test set similar to newstest2018, we took newstest2019 from the reverse translation direction German→English, swapped source and target, and concatenated it with the original test sets. This results in a new joint newstest2019 test set of 3,997 sentences.

In addition to reporting overall BLEU scores on the different test sets, we also report results on the two subsets (based on the original language) of each newstest20XX, which we call the *orig-en* and the *orig-de* halves of the test set.

Freitag et al. (2020) provided an alternative reference translation for the orig-en half of newstest2019. For both standard and alternative references, they provided an additional paraphrased 'as much as possible' version (four different references in all). In order to enable our parameter tuning experiments, we created a paraphrased version of the reference for the orig-en half of *newstest2018* (1,500 sentences) following the instructions from Freitag et al. (2020). We will release this new paraphrased reference, *newstest2018.orig-en.p*, as part of our work.



(a) Forward-translated, i.e. source original

(b) Backward-translated, i.e. target original

Figure 1: Sentences in a test set are either natural in the source and forward-translated into the target language, or vice-versa. If a test set consists of both kinds of sentences, we call it a joint test set. WMT English→German newstest2018 is a joint test set with half of the sentences being forward-translated. WMT English→German newstest2019 is a forward-translated test set.

3.2 Models

For our translation models, we adopt the transformer implementation from *Lingvo* (Shen et al., 2019), using the transformer-big model size (Vaswani et al., 2017). We use a vocabulary of 32k subword units and exponentially moving averaging of checkpoints (EMA decay) with the weight decrease parameter set to $\alpha = 0.999$ (Buduma and Locascio, 2017). We used a batch size of around 32k sentences in all our experiments.

We report BLEU (Papineni et al., 2002) in addition to human evaluation. All BLEU scores are calculated with sacreBLEU (Post, 2018)[1].

3.3 Human Evaluation

To collect human rankings, we ran side-by-side evaluation for overall quality and fluency. We hired 20 linguists and divided them equally between the two evaluations. Each evaluation included 1,000 items with each item being rated exactly once. We acquired only a single rating per sentence from the professional linguists as we found that they were

[1]BLEU+case.mixed+lang.ende+numrefs.1+smooth.exp+SET+tok.13a+version.1.4.12 SET ∈{wmt18, wmt19, wmt19/google/ar, wmt19/google/arp, wmt19/google/wmtp}

more reliable than crowd workers (Toral, 2020). We evaluated the orig-en sentences corresponding to the official WMT-19 English→German test set (Barrault et al., 2019). Results in this natural translation direction are more meaningful as pointed out by Zhang and Toral (2019), who show that translating a 'translationese' source is simpler and should not be used for human evaluation.
Our human evaluation followed the protocol:

- Fluency: We present two translations of the same source sentence to professional linguists without showing the actual source sentence. We then ask the rater wether they prefer one of the outputs or rate them equally based on fluency.
- Overall Quality: We present two translations along with the source and ask the raters to evaluate each translation on a 6-point scale. A score of 6 will be assigned to translations with 'perfect meaning and grammar', while a score of 0 will be assigned to 'nonsense/ no meaning preserved' translations. The average over all ratings yields the system's final quality score.

4 Experimental Results

This section first presents our main result comparing the same system tuned with BLEU on standard versus paraphrased references. We then break down how system design choices impact each metric differently. Throughout, we refer to scores computed with standard references as BLEU, and those computed with paraphrased references as BLEUP.

4.1 Overall Performance

We compare the performance of a system optimized on newstest2018 with standard references (opt-on-BLEU) with one optimized on newstest2018.orig-en with paraphrased references (opt-on-BLEUP). Both systems were developed using only newstest2018 data, keeping newstest2019 as a blind test set. Table 1 summarizes the results on newstest2019. Details of how these two systems were developed and how they differ are given in Section 4.2.

The opt-on-BLEU system outperforms opt-on-BLEUP by 5.2 BLEU points. Normally this would lead us to discard opt-on-BLEUP. However, the BLEUP scores tell a different story: opt-on-BLEUP outperforms by 0.3 points, a potentially large improvement given the smaller natural range of this metric. Under a significance test with random approximation (Riezler and Maxwell III, 2005), both the BLEU and BLEUP differences are significant at p<5e-18.

	opt-on-BLEU	opt-on-BLEUP
BLEU	**45.0**	39.8
BLEUP	13.4	**13.7**
human quality	4.27	**4.72**
human fluency	27.2%	**63.8%**

Table 1: BLEU scores and human ratings for WMT newstest2019 English→German (original English sources). We optimized the system to perform best on either newstest2018 with standard reference translations (opt-on-BLEU) or newstest2018.orig-en with paraphrased reference translations (opt-on-BLEUP). BLEU differences are significant according to random approximation (Riezler and Maxwell III, 2005) with p<5e-18. Human score differences are significant according to a Wilcoxon rank-sum test with p<5e-18.

Freitag et al. (2020) showed that BLEU scores calculated on paraphrased references have higher correlation with human judgment than those calculated on standard references. To verify their findings, we ran a human evaluation for the two different outputs on 1,000 sentences randomly drawn from newstest2019 (orig-en), as described above. As shown in Table 1, opt-on-BLEUP is consistently evaluated as better for both quality and fluency. To measure the significance between the two ratings, we ran a Wilcoxon rank sum test on the human ratings and found that both improvements are significant with p<e-18.

This experiment demonstrates that we can actually tune our MT system on paraphrased references to yield higher translation quality when compared to a typical system tuned on standard BLEU. Interestingly, the BLEU score for the better system is much lower, supporting our contention that BLEU rewards spurious translation features (e.g. monotonicity and common translations) that are filtered out by BLEUP.

4.2 Analysing Performance

We now describe the individual model decisions that went into the two final systems of Section 4.1. To build a classical system optimized on BLEU with standard references, we replicate the WMT 2019 winning submission (Ng et al., 2019) and examine

the effect of each of its major design decisions.[2] In particular, we are looking into the effect of data cleaning, back-translation, fine tuning, ensembling and noisy channel reranking. We examine the impact of each method on BLEU and BLEUP. For our experiments, we used newstest2018 as our development set and newstest2019 as our held-out test set. All model decisions (checkpoint, variants) are solely made on newstest2018.

Experimental results are presented in Table 2. As described in Section 3.1, we report 4 different BLEU scores for newstest2018 (dev) and newstest2019 (test). In addition to reporting BLEU score on the joint or the orig-de/orig-en halves of the test sets, we also report BLEU scores that are calculated on paraphrased references (BLEUP).

4.2.1 Data Cleaning

For data cleaning, we used CDS (Wang et al., 2018). We trained a CDS model for English→German taking news-commentary as the in-domain/clean data set. We scored all parallel sentences with our trained CDS model and kept the 70% highest scoring sentences. Our experimental results suggest that data cleaning is useful for all four types of test sets and consistently improves over a baseline system that is trained on raw parallel data. We conclude that data cleaning is useful for all systems independently of which test set it will be optimized for.

4.2.2 Back-Translation

We trained a strong German→English model on the same parallel data (with flipped source/target) and used that model to (back-)translate (BT) all deduped German monolingual sentences from NewsCrawl 2007-2018 into English. We filtered sentences with a source-target ratio lower than 0.5 or higher than 1.5. We further run language identification and filtered out all backtranslations going into the wrong language. We then oversample our bitext data to match the size of the backtranslation data and train a NMT model on the concatenation of both datasets.

As previously reported by (Freitag et al., 2019; Bogoychev and Sennrich, 2019), the original language of the sentences within a test is crucial and can lead to very different conclusions, in particular for back-translation systems. This difference is visible when looking at the BLEU scores on the standard references. While the BLEU score on orig-de does improve by 7.5 points, the BLEU score drops by 2.9 points on the orig-en half. Due to the big gain on the orig-de half, BT also improves the BLEU score on the joint set. The paraphrased references were designed to overcome these kinds of mismatches and they show a gain of 0.5 BLEU points. We can conclude that back-translation helps improve BLEU and BLEUP and we include BT for systems that are optimized for both standard or paraphrased BLEU scores.

4.2.3 Fine-Tuning

Similar to (Ng et al., 2019), we fine-tuned our back-translated model on a concatenation of previous WMT testsets (newstest{2013,2015,2016,2017}) and the clean in-domain news-commentary corpus. In total, we fine-tuned the model on 330k sentences. We kept all model parameters the same (batch size, learning rate) and continued training on the fine-tuned data for one epoch. The BLEU scores on the standard references suggest a small improvement of 0.3 BLEU on the joint test set. Interestingly, the improvement is visible on the orig-en half by 0.7 points while the BLEU scores on orig-de actually drop by 1.7 points. Nevertheless, BLEUP does improve by 0.5 points, suggesting that fine-tuning is especially helpful when measuring scores with paraphrased references. Despite the small gain on standard references, we include fine-tuning in both our optimized systems.

4.2.4 Ensemble

Combining different predictions is a standard approach in MT to boost BLEU scores. We run ensemble decoding with 4 previously built models. In addition to using the 3 models described in Section 4.2.1, 4.2.2, and 4.2.3, we build a second fine-tuned model with the same approach, but different initialization.

Although ensemble decoding improves the performance on our standard references by up to 1.9 BLEU points, the quality is rated as lower by 0.3 BLEU points on the paraphrased references. We suspect that using an ensemble for decoding favors common, average language by promoting target spans where all systems agree. Paraphrase translations actually downweight the importance of this language, which seems important for agreeing with human judgments (Freitag et al., 2020). This promotion of average language and monotonic translation may explain the effectiveness of ensembling

[2] Our replication achieves 45.0 BLEU on newstest19, competitive with the reference system at 42.7 BLEU.

	newstest2018 (dev)				newstest2019 (test)			
	joint	orig-de	orig-en	orig-en.p	joint	orig-de	orig-en	orig-en.p

+ reranking of (4) (opt on BLEUP)	47.1	45.9	47.1	**14.7**	41.6	44.0	39.8	**13.7**

Table 2: BLEU scores for WMT 2019 English→German. The *joint* sets combine *orig-en* and *orig-de* subsets. The *orig-en.p* sets use paraphrased references instead of standard references. Our experiments compared *newstest2018.joint* and *newstest2018.orig-en.p* for system tuning. The standard newstest2018 and newstest2019 sets are *newstest2018.joint* and *newstest2019.orig-en*, respectively.

only for standard reference BLEU. Similar to the WMT 2019 winning submission, we include the ensemble approach in our system that is optimized on the joint BLEU scores. However, we do not include it in our system optimized on BLEUP.

4.3 Reranking

Finally, we extend the noisy-channel approach (Yee et al., 2019) which consists of re-ranking the top-50 beam search output of either the ensemble model (when tuned for BLEU) or the fine-tuned model (when tuned for BLEUP). Instead of using 4 features—forward probability, backward probability, language model and word penalty—we use 11 forward probabilities, 10 backward probabilities and 2 language model scores. Different to (Ng et al., 2019), we did not pick the re-ranking weights through random search, but used MERT (Och, 2003) for efficient tuning.

The 11 different forward translation scores come from different English→German NMT models that are replicas of the previous described models (Section 4.2.1, 4.2.2, and 4.2.3). The 10 backward translation scores come from the same approaches, but trained in the reverse direction. These 21 NMT model scores are combined with 2 language model (LM) scores. The first LM is trained on the German monolingual NewsCrawl data, while the second LM is trained on forward-translated English NewsCrawl data. The first LM should assign high scores to genuine German text, while the second LM should assign high scores to translationese German originating from English.

We first reranked the 50-best list generated by the ensemble model with MERT on newstest2018. Similar to the original WMT 2019 submission, the BLEU scores on the joint and orig-en set increase. This reranked output corresponds to our opt-on-BLEU model. Next, we reranked the 50-best list generated by the fine-tuned model with MERT on newstest2018.orig-en with paraphrased references. This led to further small increases in BLEUP, and corresponds to our opt-on-BLEUP model.

In summary, optimizing on BLEUP leads us to keep back-translation, even though evaluation with standard English-original references would have us drop it, and also leads us to drop the ensembling step. Rescoring using MERT weights learned with BLEU or BLEUP further separates the systems according to these metrics.

5 Analysis

This section confirms the results from the previous section with additional references for newstest2019 and illustrates the behaviour of our systems on individual sentences.

5.1 Alternative Reference Translations

Freitag et al. (2020) released an additional standard reference translation (AR) and two ‘paraphrase as-much-as-possible‘ reference translations for newstest2019 (WMT.p and AR.p). We used WMT.p in all our above experiments; here we report BLEU scores for all four available reference translations in table 3. The BLEU improvements between the two standard reference translations agree perfectly. Similarly, the BLEUP improvements between the two paraphrased references also coincide. This indicates that by optimizing on BLEU or BLEUP we have not somehow overfit to a specific set of reference translations or their paraphrases, but instead

have molded our model to better match a style of reference translation.

5.2 Translation Examples

This section presents translation examples from our two differently optimized systems in Table 4. The first 3 examples show sentences where opt-on-BLEUP has higher translation quality than opt-on-BLEU. One observation of (Freitag et al., 2020) was that BLEU scores calculated on standard references prefer monotonic translations. This is visible in our first translation example, where opt-on-BLEU incorrectly translates the saying *Tomorrow's a different beast* into *Morgen ist ein anderes Biest*, using an inappropriately monotonic strategy. On the other hand, the opt-on-BLEUP system captures the meaning of the source sentence and generates a valid translation.

Another drawback of standard reference BLEU is the preference for literal translation. This is visible in our second example where the word *cap* is translated into *Kappe* and *tip* into *kippen*. Both are valid word-by-word translations, but do not make much sense in this context. The third example is another example of the monotonic translation style of a regular tuned system. The opt-on-BLEU translation is an incorrect word-by-word translation. The opt-on-BLEUP system is able to introduce a German natural sentence structure and generate a flawless translation.

The last translation example is a loss for the paraphrased-tuned system and demonstrates that sometimes a more literal translation can be better. Even though the word *run* can be translated into *Ansturm*, it is not appropriate in this context and the simpler translation *Lauf* is correct.

5.3 Matched n-grams

The BLEU scores calculated on the two different references yield different conclusions. BLEU on standard references evaluated opt-on-BLEU higher by more than 5 BLEU points. BLEUP came to a different conclusion and gave a higher score to opt-on-BLEUP. In this section, we look at the n-grams that contributed most to these different outcomes. Those that contribute most to the difference in BLEU across the two systems are:

- **Er sagte, dass** (*He said that*)
- **, sagte er der** (*, he said the*)
- **stellte fest, dass** (*noted that*)

These are all generic, high-frequency n-grams. They are crucial for attaining high BLEU scores, and tend to appear in translations that employ the same structure as the source sentence. In contrast, the n-grams that contribute most to the difference in BLEUP are:

- **Menschen ums Leben kamen** (*humans died*)
- **Grossbritanien keine Steuern zahlen** (*Great Britain pay no tax*)
- **von BBC Scottland** (*from BBC Scottland*)

These are much less frequent sequences with more semantic content.

6 Conclusions

Prior work has shown that BLEU measured on paraphrased references (BLEUP) has better correlation with human evaluation than BLEU measured on regular references (BLEU) for the comparison of *existing* systems (Freitag et al., 2019). Motivated by this finding, we collected a development set of paraphrased references and assessed BLEUP for *system development*. This allowed us to evaluate if the design choices of a modern neural MT system impact BLEU and BLEUP differently, including tuning a re-ranking noisy channel model to these metrics. Our experiments followed the setup from the winning newstest19 English→Germam entry at WMT19 (Ng et al., 2019).

For design choices, we observe that BLEUP seems to emphasize the importance of back-translation even when test sets are source original. On the other end, BLEUP seems to de-emphasize the importance of ensembles, as the reliable prediction of common language by ensembles is less rewarded by this metric.

Our tuning experiments led to positive results. In human evaluation, the system tuned on BLEUP showed significant improvements in terms of adequacy and even greater gains in terms of fluency compared to the system tuned on BLEU. Example translations indicate that the model tuned on BLEUP produces noticeably less literal translations. Our experiments also highlight a disconnect between regular BLEU and human evaluation: the system tuned on BLEUP degrades standard BLEU scores by over 5 points, while faring significantly better in human evaluation. Paraphrased automatic evaluation therefore seems to be a promising proxy

opt on BLEU	Er durchschnittlich 5,6 Punkte und 2,6 Rebounds ein Spiel in der vergangenen Saison.
opt on BLEUP	In der vergangenen Saison erzielte er im Schnitt 5,6 Punkte und 2,6 Rebounds pro Spiel.
source	Thirty-two percent supported such a run.
opt on BLEU	32 Prozent unterstützten einen solchen Lauf.
opt on BLEUP	32 Prozent sprachen sich für einen solchen Ansturm aus.

Table 4: Example output for English→German for systems optimized on standard BLEU or BLEUP. Translations for opt-on-BLEU tend to be more literal, and adhere closely to the source sentence structure.

for human evaluation when making design choices for MT systems.

This research opens the question of whether these results can be confirmed over a wide range of language pairs. We also hope to achieve further improvements by refining the paraphrased evaluation protocol.

Abstract

Users of machine translation (MT) may want to ensure the use of specific lexical terminologies. While there exist techniques for incorporating terminology constraints during inference for MT, current APE approaches cannot ensure that they will appear in the final translation. In this paper, we present both autoregressive and non-autoregressive models for lexically constrained APE, demonstrating that our approach enables preservation of 95% of the terminologies and also improves translation quality on English-German benchmarks. Even when applied to lexically constrained MT output, our approach is able to improve preservation of the terminologies. However, we show that our models do not learn to copy constraints systematically and suggest a simple data augmentation technique that leads to improved performance and robustness.

1 Introduction

Automatic post-editing (APE) aims to improve the quality of the output of an arbitrary machine translation (MT) system by pruning systematic errors and adapting to a domain-specific style and vocabulary (Simard et al., 2007; Chatterjee et al., 2018). Although previous work has shown the usefulness of APE to prune errors by focusing on improving the translation error rate (TER), few have studied the effect of incorporating lexical constraints.

There are several use cases where such a system would be beneficial. For example, content providers meticulously curate lists of terminologies for their domains that indicate preferred translations for technical terms. Lexically constrained APE would also be useful for cross-lingual information retrieval. When displaying snippets from retrieved documents, the query term should appear in the translation output (if it does in the source) as it can make relevance clear to the end user. Here, the query serves as the term.

While recent approaches allow inference time adaptation of NMT systems using these terminologies (Dinu et al., 2019; Post and Vilar, 2018), post-editing translations with a generic APE system may lead to dropped terms. A constraint-aware APE system would allow to fix systematic translation errors, while keeping the terminologies intact.

Inspired by Dinu et al. (2019), we consider a range of representations which augment input sequences with constraint tokens and factors for use in an autoregressive Transformer (AT) APE model. Using this approach, the constraints are explicitly represented in the encoder input sequence, and the model learns to prefer translations that contain the supplied terminologies during decoding. We also explore the use of the Levenshtein Transformer (LevT) (Gu et al., 2019), a non-autoregressive Transformer (NAT) model. The LevT model applies neatly to the APE task since the decoder can be initialized with an incomplete sequence to be refined. Additionally, multiple corrections can be made simultaneously, yielding a decoding speedup over autoregressive models.

We then show that constrained APE improves translation quality and terminology preservation on top of both unconstrained and constrained MT. While both constrained and unconstrained APE models perform similarly on reducing systemic errors in the MT output, they differ in their ability to preserve terminology constraints. When applying unconstrained APE on top of constrained MT, we find a 12.6% relative drop of supplied terminology constraints as compared to a fully constrained MT to APE pipeline.

We experiment extensively with variations of both AT and LevT models, testing on both PBMT and NMT English to German WMT APE tasks (Chatterjee et al., 2018). Under all scenarios, the model performs post-editing while satisfying terminology constraints when supplied.

Proceedings of the 5th Conference on Machine Translation (WMT), pages 1193–1204
Online, November 19–20, 2020.

Our evaluation of both constrained AT and NAT models on PBMT and NMT APE benchmarks shows that both models correctly translate more than 95% of terminology constraints, with the NAT model achieving the highest coverage of terminologies at the expense of post-editing quality.

Finally, using constraints constructed with synonyms and antonyms, we show that our models do not learn to copy constraints systematically, and introduce a simple data augmentation strategy to improve the preservation of unusual constraints.

To summarize, our contributions are as follows:

1. We propose the terminology constrained APE task and evaluate several AT and LevT model variants for incorporating lexical constraints.

2. We empirically show that constrained APE is necessary to preserve terminology constraints in a MT to APE pipeline.

3. We analyze the robustness of the constraint translation behavior and suggest a simple data augmentation technique that both improves translation quality and increases the number of correctly translated terms.

2 Related Work

2.1 MT with Terminology Constraints

Integrating terminology constraints into translation can be divided into two approaches: constrained decoding and input sequence modification.

Constrained decoding modifies the decoding process to enforce the generation of the specified terminologies. This includes methods that modify beam search, such as grid beam search (Hokamp and Liu, 2017) and dynamic beam allocations (Post and Vilar, 2018). While these approaches are effective in including terminologies, they come with an increase in inference time due to the added overhead in the search algorithm.

The LevT (Gu et al., 2019), which uses a non-autoregressive decoding procedure, can initialize its decoder with a partial or incomplete output sequence. By initializing the decoder output with terminology constraints, Susanto et al. (2020) train a LevT model to perform constrained decoding. Unlike constrained search methods in autoregressive models, this initialization technique does not add any significant overhead to the decoding process. When modified to disallow deletion of terms and insertion between consecutive terminology tokens, LevT is able to retain all terminologies without affecting the performance and speed.

Alternatively, Dinu et al. (2019) propose modifying the encoder input sequence to represent terminology constraints. During training, the model learns to identify constraints in the input sequence, and translate them appropriately during decoding. This approach has the benefit of not adding additional overhead during inference.

2.2 Automatic Post-Editing

The APE task has gone through many iterations, since it was originally proposed by Simard et al. (2007). Initially, the task was to improve an unknown phrase-based machine transition (PBMT) system. An additional task to fix errors of an NMT system was introduced at WMT 2018 (Chatterjee et al., 2018).

For the APE tasks, the use of the multi-source variant of the neural encoder-decoder model is the most popular approach (Bojar et al., 2017), with the Multi-source Transformer (MST) instantiation (Junczys-Dowmunt and Grundkiewicz, 2018) achieving state-of-the-art results in 2018. Based on the AT model (Vaswani et al., 2017), the MST model consists of two Transformer encoders and a single decoder. The source sentence and the MT system output are fed separately to the two encoders, where the outputs are concatenated and then fed into the decoder to perform post-editing.

Recent work has explored alternative architectures for APE. The winner of 2019 APE tasks (Lopes et al., 2019), for example, uses a BERT-based encoder and decoder. Gu et al. (2019) both introduce the LevT model and demonstrate its utility on an APE task.

3 Constrained APE

The task of APE is to correct systematic errors in an MT system output. An APE model takes as input two sequences: the source language sentence to be translated and the translation of this sentence into the target language by an MT system. The intended output is a corrected version of the MT system's initial translation (Simard et al., 2007).

Constrained APE allows for the specification of terminology constraints: a translation for one or more phrases in the source language input may be pre-specified as additional input. The constrained APE model must use the supplied terminology constraints when performing the APE task.

Figure 1: An example of the inputs and output for the constrained APE task. Source is the source sentence. Post-Edit is the corrected MT sentence. We show the *Append* and *Replace* method to incorporate terminologies on the source side. Factors indicated for each word as source word (0), source constraint (1), target constraint (2), and MT word (3). The terminology pair for this example is (*features*, *Funktionen*).

Formally, let $\mathbf{x} = [x_1, \ldots, x_m]$ and $\boldsymbol{\gamma} = [\gamma_1, \ldots, \gamma_n]$ be the source language sentence and the initial MT translation respectively. The tokens x_i and γ_i are drawn from the source and target language vocabularies $\mathcal{S}$ and $\mathcal{T}$ respectively. The target post-edited sentence is a sequence $\mathbf{y} = [y_1, \ldots, y_o]$, with tokens y_i also drawn from $\mathcal{T}$.

We are also given a series of t translation constraints, $\mathcal{C} = \left\{\left(\check{\boldsymbol{x}}^{(1)}, \check{\boldsymbol{y}}^{(1)},\right), \ldots, \left(\check{\boldsymbol{x}}^{(t)}, \check{\boldsymbol{y}}^{(t)},\right)\right\}$, where each constraint $\left(\check{\boldsymbol{x}}^{(i)}, \check{\boldsymbol{y}}^{(i)}\right) \in \mathcal{S}^* \times \mathcal{T}^*$ is a tuple of source language phrase, $\check{\boldsymbol{x}}^{(i)} = [\check{x}_1, \ldots, \check{x}_j]$, and its desired translation, $\check{\boldsymbol{y}}^{(i)} = [\check{y}_1, \ldots, \check{y}_k]$, into the target language.

The goal of the constrained APE task is to learn a mapping of $\mathbf{x}, \boldsymbol{\gamma}$, and $\mathcal{C}$ to the target post-edited translation $\mathbf{y}$. Crucially, when a source side constraint $\check{\boldsymbol{x}}^{(i)}$ matches a sub-sequence in $\mathbf{x}$, it is required that the sub-sequence be translated as $\check{\boldsymbol{y}}^{(i)}$. See Figure 1 for an example.

4 Models

While there are existing models to address the APE task, and the lexical constrained MT task, it is not clear how to represent lexical constraints for APE models which, unlike MT models, take two sequences as input. We propose several techniques to incorporate constraints as additional inputs to the APE encoder by combining the input sequence modification used in constrained MT (Dinu et al., 2019) with the MST method of (Tebbifakhr et al., 2018). For decoding, we experiment with both the AT and the LevT decoders. The LevT decoder can additionally take advantage of different decoder initialization strategies for constrained decoding.

We first briefly show how we encode terminology constraints in the input sequence, before describing how they are incorporated into the MST and LevT APE models specifically.

Model	Input	Init.
MST	$\mathbf{x}, \boldsymbol{\gamma}$	–
MST Append	$\mathbf{x}^+, \boldsymbol{\gamma}$	–
MST Replace	$\mathbf{x}^-, \boldsymbol{\gamma}$	–
LevT	$\mathbf{x}$	$\boldsymbol{\gamma}$
LevT Append	$\mathbf{x}^+$	$\boldsymbol{\gamma}$
LevT Replace	$\mathbf{x}^-$	$\boldsymbol{\gamma}$
MS LevT	$\mathbf{x}, \boldsymbol{\gamma}$	$\check{\boldsymbol{y}}^1, \ldots, \check{\boldsymbol{y}}^{(t)}$

Figure 2: Setup for the models by the input and initialization at inference.

4.1 Encoding Lexical Constraints for APE in the Input Sequence

In the APE setting, the input to the model is the source language sentence $\mathbf{x}$ and its initial MT translation $\boldsymbol{\gamma}$. We also need to represent in $\mathbf{x}$ the translation constraints $\mathcal{C}$.

For clarity, we describe the case of representing a single translation constraint $(\check{\boldsymbol{x}}, \check{\boldsymbol{y}})$ where $\check{\boldsymbol{x}} = [\check{x}_1, \ldots, \check{x}_j]$ is a source language constraint and $\check{\boldsymbol{y}} = [\check{y}_1, \ldots, \check{y}_k]$ is its target language translation. Our approach trivially generalizes to multiple constraints. We represent the constraint $(\check{\boldsymbol{x}}, \check{\boldsymbol{y}})$ in $\mathbf{x}$ in one of two ways. Either by appending the target language constraint $\check{\boldsymbol{y}}$ after the occurrence of $\check{\boldsymbol{x}}$ in the input sequence, or by replacing occurrences of $\check{\boldsymbol{x}}$ in $\mathbf{x}$ with $\check{\boldsymbol{y}}$.

For example, if we had the constraint, $(\check{\boldsymbol{x}}, \check{\boldsymbol{y}}) = ([\check{x}_1, \check{x}_2], [\check{y}_1])$ and the source input $\mathbf{x} = [x_1, x_2, x_3, x_4]$, with $[\check{x}_1, \check{x}_2] = [x_2, x_3]$, we would obtain the following input sequences for the append

and replace methods:

- *(Append)* $\mathbf{x}^{+} = [x_1, x_2, x_3, \breve{y}_1, x_4]$
- *(Replace)* $\mathbf{x}^{-} = [x_1, \breve{y}_1, x_4]$.

To further differentiate the constraint terms from other tokens in the source sentence, a "source factor" is associated with each input token. The source factor is equal to 1 or 2 to indicate a source or target side terminology constraint, while 0 indicates an unconstrained source token. For the above examples, we would obtain the following source factors:

- *(Append)* $\mathbf{s}^{+} = [0, 1, 1, 2, 0]$
- *(Replace)* $\mathbf{s}^{-} = [0, 2, 0]$.

The source input sequence and source factor sequence are separately embedded and concatenated before they are fed into the encoder. See Figure 1 for examples of the *append* and *replace* methods applied to a source sentence.

We now describe how we use these modified input sequences in the MST and LevT models. See Figure 2 for an overview of the the proposed models and their configuration.

4.2 Multi-source Transformer

The input to an APE model is a pair of sequences, the source sentence and the MT output to be post-edited. To accommodate these two sequences, we use the MST model of Tebbifakhr et al. (2018), which uses a separate Transformer to encode each sequence. The outputs of each encoder are concatenated and attended to by the decoder.

We augment the encoder for the source sentence with the *append* and *replace* methods. Figure 1 shows an example of the inputs for the *append* and *replace* methods, $\mathbf{x}^{+}$ and $\mathbf{x}^{-}$ respectively. To account for the additional input of MT, $\boldsymbol{\gamma}$, for the source factors, we use 3 for each token in $\boldsymbol{\gamma}$. For Byte-Pair Encoding (BPE) (Sennrich et al., 2016), the corresponding source factor token is applied for all subword units.

We train three variants based on MST: an unconstrained version as the baseline (MST), and two constrained versions using the *append* (MST Append) and *replace* (MST Replace) methods as described in subsection 4.1.

4.3 Levenshtein Transformer

The LevT follows the Transformer encoder-decoder architecture. However, instead of a regular Transformer decoder, the model uses three consecutive layers to simulate the edit operations. The first layer predicts whether each token should be deleted or kept. The second layer predicts how many placeholder tokens to insert between every two consecutive tokens. The final layer then predicts the actual target token for each placeholder.

One benefit of using the LevT is its ability to initialize the decoding process with an arbitrary sequence. The first iteration of the decoding process is typically initialized with $\mathbf{y^0} = [<s>, </s>]$, but it is possible to initialize it with MT (i.e. $\boldsymbol{\gamma}$) and allow it to be subsequently refined.

Since LevT retains the single encoder and decoder structure, the changes to incorporate lexical constraints are straightforward; we apply the *append* and *replace* methods to the encoder input.

We also try augmenting the LevT similarly to the MST. Here, we have two encoders for the source, $\mathbf{x}$, and MT, $\boldsymbol{\gamma}$, respectively. During inference, we initialize the decoding string with target-side constraint terms, $\breve{\boldsymbol{y}}$, similar to the constrained decoding setup in Susanto et al. (2020).

For multiple constraints, we sort the target side terms $\breve{\boldsymbol{y}}^{(i)}$ by the order of the occurrence of $\breve{\boldsymbol{x}}^{(i)}$ in the source $\mathbf{x}$. When source and target word order diverge, we hope that the model will learn to reorder constraints correctly, but leave experimentation with constraint ordering for future work.

We train four variants of the LevT model. An unconstrained baseline model (LevT), and two constrained variants, with the same architecture as the base LevT, that incorporate constraints in the source using the *append* $(\mathbf{x}^{+})$ (LevT Append) and *replace* $(\mathbf{x}^{-})$ (LevT Replace) methods described in subsection 4.1. The decoder initialization for these models is the MT sentence, $\boldsymbol{\gamma}$, that needs to be edited. The final variant has a multi-source encoder, where $\mathbf{x}$ and $\boldsymbol{\gamma}$ are fed into separate encoders. The decoder in this case is initialized with the target sequence of the terminology constraint(s).

5 Data

5.1 APE Datasets

We use two standard English-to-German APE benchmark datasets, WMT18 PBMT (Chatterjee et al., 2018) and WMT19 NMT (Chatterjee et al., 2019). Both datasets are in the IT domain. Each example from these datasets consists of three sequences: (1) the source sentence $\mathbf{x}$, (2) its MT output $\boldsymbol{\gamma}$, and (3) its post-edited target $\mathbf{y}$.

Dataset		# of Triplets			Term%	TER	BLEU
		Train	Valid	Test			
PBMT	artificial 4M	4,390,180	1,000	-	-	-	-
	artificial 500K	526,368	-	-	-	-	-
	WMT'18 APE	24,000	2,000	2,000	88.83	24.57	62.39
NMT	eSCAPE NMT	4,999,102	1,000	-	-	-	-
	WMT'19 APE	13,442	1,000	1,023	89.52	16.92	74.60

Table 1: Statistics for data used. Term%, TER, and BLEU are provided for do-nothing case of test set.

Since the official collections are relatively small, we augment them with large synthetic datasets for pretraining: artificial (Junczys-Dowmunt and Grundkiewicz, 2016) and eSCAPE (Negri et al., 2018). The artificial dataset is generated using round-trip translation of two PBMT systems. It is already cleaned and tokenized. The eSCAPE dataset, containing 7,258,533 triplets, is created using NMT generated output from various parallel corpora. The data for eSCAPE is noisy, and we follow Lee et al. (2019)'s procedure to filter the dataset, which results in around 5 million triplets. We then tokenize the filtered data using Moses (Koehn et al., 2007).[1] For pretraining on the synthetic corpora, we set aside 1,000 randomly sampled triplets as our validation set. Table 1 summarizes the statistics of both the evaluation and pretraining datasets.

For both tasks, we use the same preprocessing steps. After tokenization, we truecase the data using Moses. We then use BPE with 32,000 merge operations on the joined vocabulary of source and target language.

5.2 Terminology Dataset

We create terminology sets for each APE dataset using Wiktionary.[2] We follow the procedure of Dinu et al. (2019), finding term translation pairs $(\check{\boldsymbol{x}}, \check{\boldsymbol{y}})$ in Wiktionary such that $\check{\boldsymbol{x}}$ is present in the source sentence $\mathbf{x}$ and $\check{\boldsymbol{y}}$ is present in the post-edited target sentence $\mathbf{y}$. We ignore stop words that appear on the source and target side. To include more morphological variations, we include matches on stemmed versions of $\check{\boldsymbol{x}}$ and $\check{\boldsymbol{y}}$ using Snowball stemming.[3] We recover the unstemmed words from the pairs to be included in the terminology dataset. In order for the model to perform the APE task well when no constraints are supplied, we keep only 25% of matched terminology constraints (i.e. we remove 75% of constraints at random).

We split the terminology dataset into training and test sets so that terminology constraints provided at test time are not seen during training. We only use the training set for the training corpora of APE datasets, and use the test sets of the terminology on the validation and test set of the APE datasets. See Table 2 for statistics of terminology coverage on the training, validation, and test splits.

With the given MT system, we can evaluate on terminology percentage for the do-nothing case, which is shown in Table 1. The original MT model already achieves a high term percentage of around 90% for PBMT and NMT tasks.

6 Experiments

We use the FAIRSEQ toolkit (Ott et al., 2019) for implementing the MST and extending the LevT.[4] We evaluate the models on translation error rate (TER) (Snover et al., 2006) and BLEU (Papineni et al., 2002) using the official evaluation script[5] for analyzing the post-editing performance. We also compute the percentage of target language term constraints present in the output (Term %) to measure the performance of the constrained models.

6.1 Constrained MT-to-APE Cascades

In our first experiment, we attempt to demonstrate the utility of constrained APE when applied to constrained MT. That is, we have some terminology constraints that we want to preserve throughout the application of MT and subsequent APE. We

conjecture that unconstrained APE applied on top of constrained MT will potentially discard or re-translate previously translated constraints.

We experiment with all possible pipelines of MT to APE, i.e. the product of $\{\text{MT}, \text{Const. MT}\} \times \{\text{No APE}, \text{APE}, \text{Const. APE}\}$ with six total pipelines possible.

MT Models To obtain MT models for this experiment we train both a constrained and unconstrained AT MT model using the default FAIRSEQ Transformer hyperparameters and use the embedding size of 16 for the source factor embedding. We follow the settings of Dinu et al. (2019), training an unconstrained transformer and a constrained model with append method to perform English-to-German translation using the Europarl and News Commentary data, and using the WMT 2013/2017 test set as validation and test set respectively. The preprocessing steps follows that of the APE datasets.

For the constrained MT model we used the *append* input modification method to make the model constraint aware. Terminology constraints are generated according to the method described in subsection 5.2. Dinu et al. (2019) also released their Wiktionary terminology set (Wikt975)[6] and we also show evaluation results using this terminology collection. We report BLEU and terminology coverage (Term %) for our MT models on the WMT 2017 test set in Table 3.

APE Models We use the MST and the append method as the unconstrained APE and constrained APE respectively. We evaluate the MT to APE pipelines using the WMT'19 APE test set, replacing the provided MT in the triplet with the outputs from our unconstrained or constrained MT models.

Table 3: Translation result of vanilla and lexically constrained translation.

We train the APE models using the eSCAPE corpus, where 1,000 triplets are used as validation set. We use the default FAIRSEQ Transformer hyperparameters. For the constrained APE, we use the embedding size of 16 for the source factor tokens.

6.2 Benchmark APE Tasks

The APE models are trained in two step fashion. First, a general APE system is trained using a synthetic dataset until convergence. Then the model is refined on the official dataset. For the PBMT task, we follow the training procedure of Gu et al. (2019). The model is pretrained on the artificial 4M dataset, and fine-tuned on the joined dataset of the 500K artificial dataset and the 10 times up-sampled official PBMT data. For the NMT task, we pretrain on eSCAPE and fine-tune on the official NMT data.

We use the default Transformer parameters for the MST variants, with an embedding size of 16 for source factors of the constrained APE models. For the LevT models, we follow the same setup and hyper-parameters as described in Gu et al. (2019).

We compare our models to the do-nothing case, where the output of the MT, γ, is treated as the predicted post-edited sentence $\hat{\mathbf{y}}$. The unconstrained variant also serve as a basis for comparing the performance of the constrainted APE models. We also compare our models to the winning system for the tasks, MS_UEdin (Junczys-Dowmunt and Grund-

7 Results and Discussions

7.1 Constrained MT-to-APE Cascade

Table 4 shows the result of the various combinations of MT and APE systems. Since the MT system is trained on news/parliamentary proceedings and not on the IT domain of the APE data, the translation quality is relatively low. Nevertheless, the constrained MT can include almost twice as many terminologies as the original model. Both APE systems improve the quality of the MT outputs, with constrained APE performing slightly better. However, constrained APE excels at including terminologies, as it consistently increases the terminology percentage from the previous MT output. When supplied with a constrained MT, the vanilla APE actually decreases the percentage of correct terminologies by 9% (86.33% to 77.22%), whereas the constrained APE model can increase it by 2% (86.33% to 88.38%).

7.2 Benchmark APE on PBMT Output

Table 5 shows the results on the PBMT task. All MST variants improve from the do-nothing case, where the output is unchanged, i.e.$\gamma = \hat{\mathbf{y}}$. Using either the *append* or *replace* methods shows similar improvements in Term%, increasing about 7% points absolutely over the do nothing case. The terminology aware MST models also see small decreases in TER and small increases in BLEU relative to the unconstrained MST model. These results are encouraging as it shows that introducing terminology constraints does not interfere with the APE system's ability to fix systematic errors.

We were unable to reproduce the result by Gu et al. (2019); we see only small improvements with

Models	Term%↑	TER↓	BLEU↑

Table 6: Results for NMT 2019.

the LevT models relative to the do-nothing case. Additionally, the *append* and *replace* variants yield only small increases in Term% but are around 4-5% points behind the equivalent MST model. The MS LevT, however, achieves the highest terminology percentage of all models, while slightly underperforming the MST models on TER and BLEU.

None of our proposed models beat the SOTA baseline for this task on TER or BLEU, but our best model on TER, MST Append, is less than 1 percentage point worse in TER. At the same time, MST Append successfully translates 6.8% more terminology constraints than the SOTA baseline.

7.3 Benchmark APE on NMT Output

Table 6 shows the result of the NMT task. This is a more difficult post editing task as the machine translated text from NMT systems is of a higher quality than PBMT systems, and the official training corpus is smaller than that of PBMT APE (Chatterjee et al., 2018). As further evidence of the difficulty of this task, the winning system of the WMT2019

Antonym	wenn Sie den Bildprozessor verwenden , können Sie die Dateien direkt im JPEG-Format in der gewünschten Größe **löschen**

Figure 4: Example of data augmentation. The original term pair is (*save*, *speichern*). We replace the target terminology *speichern* with the synonym *sichern* (to store for future use) or the antonym *löschen* (to delete).

APE shared task is able to achieve a mere 0.78 point decrease in TER.

The two terminology-aware MST models (*append* and *replace*) are able to improve Term% over the baseline, at the cost of a slight increase in TER and decrease in BLEU, but both are better than doing nothing. The LevT and its variants perform worse than doing nothing in terms of TER and BLEU, but has a small gain in Term%. The MS LevT again achieves the highest Term% but does worse than the do-nothing case on TER and BLEU.

8 Analyzing Constraint Translation Behavior

Terminology constrained APE aims to add some degree of user control over the APE process without destabilizing the general post-editing behavior of the decoder. However, the imposition of rare or unusual terminology constraints will necessarily be in conflict with the decoder language model, which will give higher probabilities to terminology translations found frequently in the training data.

In practice, a user may specify a terminology constraint that is not well represented in the training distribution. For example, a user may want a product description translated using location specific brand names or marketing copy. Ideally, a terminology constrained model would reliably produce these terms and use them appropriately even if they do not rank highly by the decoder.

Additionally, it is desirable that the addition of terminology constraints does not lead to large changes in the model's output. Since terminology constraints are only bound to a word or phrase, the model should only need to make minimal changes between the unconstrained and constrained output. Large changes in output may make it harder for a user to anticipate the effects of a constraint which may make constrained APE less useful in practice.

Table 8: Structural change from the output of constrained models using the correct terminology. We split the dataset by synonyms and anotnyms, consisting of 191 and 45 samples respectively.

We refer to this behavior as *systematic copying*, i.e. the model should behave in a transparent and stable way, enforcing terminology constraints even when they strongly disagree with the decoder language model, while only making minimally necessary changes in the output to do so.

By harvesting terminology constraints from the training data, we run the risk that the model simply learns to draw some translation hints from the supplied terminology constraints, but does not actually learn this systematic copying behavior. That is, it never truly sees an out-of-sample constraint that is extremely unlikely from the perspective of the decoder language model.

To test whether our proposed models indeed learn this systematic copying behavior we perform a qualitative experiment, comparing model outputs when supplying different constraints for a source word, by varying whether the target language constraint was (a) the original target language constraint specified in the test set, (b) a target language synonym of the original constraint term, (c) a target language antonym of the original constraint term, or (d) a totally random term in the target language.

While antonym and random term constraints might not seem to correspond to realistic use cases, they let us to examine the effects of specifying a constraint where the source and target language terms are extremely semantically divergent. Additionally, they simulate scenarios where translations for names vary dramatically by region. For example, the cleaning product called "Mr. Clean" in the U.S. is called "Meister Proper" in Germany.

As can be seen in Figure 3, our qualitative exploration reveals that synonym, antonym, and random terminology constraints are frequently not included in the output. For example the MST model fails to generate the antonym *Verkleinerung*. This suggests that target side constraints that are unseen during training may be ignored by the model, and that the models are not learning to systematically copy arbitrary constraints.

8.1 Data Augmentation Experiment

The results of our qualitative exploration suggests that the model would benefit from seeing more semantically divergent terminology constraints during training. To that end, we propose a data aug-

mentation experiment to increase the robustness of the APE models. We create novel training instances by replacing the target language term constraint with either a synonym or antonym (using Wiktionary), as well as replacing it's occurrence in the post-edited target translation. This results in 837,127 additional samples for eSCAPE corpus, and 2587 additional samples for official NMT data. See Figure 4 for examples.

We then train MST append and MS LevT with the augmented pretraining corpus. We experiment with using augmented data only for pretraining (*pretrain*) and for the fine-tuning process (*ft*). The result can be seen in Table 7.

Interestingly, on the WMT19 test set, the data augmentation helps with TER and BLEU while having only a slight effect on Term%. For the LevT, data augmentation helps all metrics.

Since the WMT19 APE test data contains few unusual constraints, the effect of the augmented data is relatively small. When we create antonym and synonyms examples from the WMT19 APE test data, we see fairly positive trends, with pretraining and fine-tuning yielding additive reductions in TER and gains in BLEU. This suggests that the augmentation method has a positive effect on the systematic copying behavior of the model.

8.2 Post-Edit Stability

To quantify the stability of the APE models, we compare the constrained APE output when given a target side synonym or antonym to the output of that same model under the original test set constraint using TER and BLEU. Under this setting, higher BLEU and lower TER indicate that the model makes minimal changes when inserting a semantically divergent constraint. We also report Term% to show how often the terminology was correctly translated given the input. We refer to a model with high Term% and BLEU but low TER as a stable model. Results of this experiment are shown in Table 8.

There are several takeaways from this experiment. First, the LevT TER scores are higher on average than the MST model suggesting that the LevT model is less stable, producing different translations for each target side constraint change.

Second, as sensitivity to constraints increases (i.e. Term% goes up), TER generally goes up, implying that models make more structural changes to the overall output in order to accommodate constraints. Future work on refinement tasks like APE may benefit from including an explicit objective function to encourage output stability.

Finally, synonyms are harder to translate than antonyms (i.e. Synonym Term% is lower than Antonym Term% for all models/training configurations). This may be because the original target side constraints are better represented in the decoder language model and are likely have higher probability than a synonym when either could be plausibly used in the same context. Antonyms may be less likely and therefore easier to override the preferences of decoder.

9 Conclusion and Future Work

This work introduces the terminology constrained APE task and several MST and LevT model variants for incorporating lexical constraints during post-editing. Furthermore, we show that constrained APE is necessary for preserving lexical constraints in a MT to APE pipeline. Evaluations on standard APE benchmarks show that terminology constraints are satisfied while improving the original MT quality. Finally, we show that the constrained APE models do not learn a robust systematic copying behavior, and propose a data augmentation method to help mitigate this issue. In future work, we hope to explore ways of modifying model architecture or training algorithms to further improve the systematic copying behavior.
